Plague in Sacramento.—A case of bubonic plague was reported in Sacramento on November 6. This is the third case in the city within three months.

"Pediatrics" Changes Hands.—The appearance of the October number of *Pediatrics* marks a change in the administration of this journal. Dr. William Edward Fitch, formerly editor of *Gaillard's Southern Medicine*, has become editor, and with him are associated as editorial council, Drs. Abram Jacobi, Louis Fischer, Charles De M. Sajous, and Alfred Cleaveland Cotton, and thirty-one collaborators.

State Board of Medical Examiners of New Jersey.—At a meeting of the State Board of Medical Examiners of New Jersey, held at Newark, November 3, Dr. E. L. B. Godfrey resigned from the sec-

retaryship of the board, on account of continued ill health, and Dr. Horace G. Norton of Trenton was elected to fill the unexpired term.

The New York Department of Health was served with a writ of dispossession on November 6, 1909, ordering it to vacate its present headquarters at Sixth avenue and Fifty-fifth street. The cause was a failure to accede to an increase in rent from $20,000 to $30,000 a year demanded by the owners.

New Health Department Building.—The corner stone for a new building for the Department of Health in Brooklyn was laid recently by Mayor McClellan. Dr. Darlington and Dr. Joshua M. Van Cott spoke. The cost of the building will be about $350,000. It is of white marble, and according to the present outlook it will be ready for occupancy by January 1.

Pellagra Commission.—The Acting Secretary of the Treasury has announced the appointment of the following commission to study and report on official action necessary to arrest the progress of the disease pellagra now prevalent in the South: Passed Assistant Surgeon John S. Anderson, director of the hygienic laboratory, chairman; Surgeon M. J. Rosenau of the Marine Hospital Service, Dr. Reed Hunt, chief of the division of pharmacology, hygienic laboratory; Passed Assistant Surgeon Charles H. Lavinder, secretary of the commission; Dr. William A. White, superintendent of the Government Hospital for the Insane; Dr. Nicholas Achuccaro, specialist in nervous pathology Government Hospital for the Insane, and Passed Assistant Surgeon J. D. Long.

Charitable Bequests.—By the will of the late John Stewart Kennedy the Presbyterian Hospital of New York City is to receive the sum of $2,500,000. Other medical institutions to benefit by the bequests of Mr. Kennedy are the New York Infirmary for Women and Children, $25,000; the New York Orthopedic Dispensary, the Home for Incurables at Fordham, the Manhattan Eye and Ear Hospital, the New York Society for the Relief of the Ruptured and Crippled, $10,000 each, and the Bar Harbor Medical and Surgical Hospital, $5,000. It is further provided that if any of the private benficiaries die without issue the sums left to them shall be divided between the Presbyterian Hospital and three other institutions.

Dr. Samuel H. Gilliland of Marietta, Pa., has been appointed by the Governor of Pennsylvania State Veterinarian in succession to the late Dr. Leonard Pearson. He will also be chosen Secretary and Legislative Officer of the State Live Stock Sanitary Board and be in charge of the meat-inspection service. He was graduated from the Veterinary Department of the University of Pennsylvania in the class of 1901 and from the Medical Department in the class of 1904. Subsequently he made extensive studies abroad, especially in comparative pathology. He was for eight years Assistant Bacteriologist to the State Live Stock Board.

The International American Congress of Medicine and Hygiene will be held in Buenos Aires in 1910, the opening session occurring on May 24. The president of the congress is Dr. Eliseo Cantón, the treasurer, Dr. Eduardo Fidanza, and the general secretaries, Drs. Luis Agote and Pedro Lacavera. In connection with the congress will be held an exhibition of hygiene to which all nations are invited to contribute. Information in regard to this should be addressed to the general secretaries of the Congress.

A Pure Drug Show will be held under the auspices of the National Druggists' Exhibition Company at Madison Square Garden during the week of November 15-20. Besides an antituberculosis exhibit there will be shown the staple drugs manufactured in this country and abroad. The process of manufacture will form a conspicuous feature of the show.

Medical Women Incorporated.—The incorporation of the Women's Medical Association of New York was approved by Supreme Court Justice Truax recently, its objects being to bring into closer relation the Alumnæ of the Woman's Medical College of the New York Infirmary, as well as other women physicians holding degrees. The incorporating physicians are Drs. Mary B. Jewett, Josephine Hemenway, Eleanor Parry, Alma Vedin, Annie S. Daniels, Martha Wollstein, and Anna Williams. The annual meeting will be held in May.

The American Association of Clinical Research was organized at a meeting held in Boston on October 27, 1909. The association is composed of physicians and surgeons from both the regular and the homeopathic schools, and is organized to institute clinical research and to establish an American journal of clinical research, in which the work of members of the association and of others doing clinical research work in a scientific manner shall be published. The officers elected were: *President*, Dr. Charles H. Bangs of Lynn, Mass.; *Vice-Presidents*, Dr. W. T. Hamilton of Montreal and Dr. Stillman Bailey of Chicago; *General Secretary*, Dr. James Krauss of Boston; *Corresponding Secretary*, Dr. Francis X. Cobb of Boston; *Treasurer*, Dr. Walter Wesselhoeft of Cambridge; *Registrar*, Dr. DeWitt G. Wilcox of Boston.

The Connecticut State Medical Association, at its semi-annual meeting held at Waterbury, on October 28, 1909, elected the following officers: *President*, Dr. F. N. Loomis of Derby; *Vice-President*, Dr. Nelson A. Pomroy of Waterbury; *Member of Executive Committee* for two years, Dr. M. C. O'Connor of New Haven.

The Iowa State Health Officers' Association elected the following officers for the ensuing year: *President*, Dr. A. J. Sweney of Decorah; *Vice-President*, Dr. Fred Albert of Mason City, and *Secretary-Treasurer*, Dr. W. G. Carhart of Marion.

The East Side Physicians' Association will hold its next meeting at Scheffel Hall, 194 Third avenue, New York, on Thursday evening, November 18, 1909, at 8.30 o'clock.

Oswego Academy of Medicine.—The opening meeting of the 1909-10 biweekly session of the Oswego Academy of Medicine was held Thursday evening, October 28, with twenty members present. The subject of discussion was anterior poliomyelitis.

Obituary Notes.—Dr. Charles Henry Cobb of Boston died on November 1, 1909, aged 65 years. He was a graduate of the Harvard Medical School and professor of materia medica and therapeutics for sixteen years, and since 1901 Dean of the College of Physicians and Surgeons. He was a member of the Massachusetts Medical Society and American Medical Association.

Dr. Nicholas L. Hornsby of St. Louis, Mo., died on his farm at Carondelet, October 26, 1909.

aged 87 years. Dr. Hornsby was a graduate of the Transylvania University in 1842, and had practised in St. Louis and Carondelet since 1844.

Dr. William Coburn of Oshawa, Ontario, died at his home, October 28, 1909, after having been paralyzed for a year. Dr. Coburn was a graduate of the Medical Department of Victoria College in 1864.

Dr. Charles H. Ott of Sayre, Pa., died on November 1 at the age of 48 years. He was graduated from Jefferson Medical College in the class of 1883, and was superintendent of the Robert Packer Hospital. He was a member of the Bradford County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. James P. Booth of Los Angeles, Cal., died October 21, at his home, aged 62 years. He was a graduate of the Texas Medical College at Galveston in 1871, and was a member of the Los Angeles County Medical Society, the Medical Society of the State of California, and the American Medical Association. Dr. Booth was well known in Southern California as an editor as well as a physician.

Dr. Anderson W. Jones of Lexington, Ky., died at his home, October 22, 1909, aged 43 years. Dr. Jones was a graduate of the Jefferson Medical College in 1890.

Dr. George R. Harris of Norwich, Conn., died at his home October 27, 1909, as the result of a cerebral hemorrhage, aged 44 years. He was a graduate of the College of Physicians and Surgeons of New York, in 1885, and a member of the New London County Medical Association and the Connecticut Medical Society.

Dr. John Meader Goldsmith of Atlanta, Ga., died October 26, 1909, aged 32 years. He was a graduate of the Jefferson Medical College, in 1900, and was a member of the Fulton County Medical Society, the Medical Association of Georgia, and the American Medical Association.

Dr. Samuel S. Kahn of San Francisco died at Coronado, on October 18, 1909, aged 54 years. After graduating from the College of Physicians and Surgeons in New York, in 1877, Dr. Kahn entered the army as surgeon. He resigned, however, the next year to go to California, where he became prominent as a physician. He was a member of the San Francisco Medical Society, the Medical Society of the State of California, and the American Medical Association.

Dr. Edward P. Marston of Monmouth, Me., died, October 24, 1909, aged 47 years. He was a graduate of the Dartmouth Medical School in 1884, and was a member of the Kennebec County Medical Society, the Maine Medical Association, and the American Medical Association.

Dr. Griffith W. Patterson of Atlanta, Ga. died at his home, October 23, 1909, aged 72 years. He was a graduate of the Georgia College of Eclectic Medicine and Surgery, and a veteran of the Civil War.

Dr. William E. Scobey of Kankakee, Ill., died at his home, October 25, 1909, aged 77 years. He was a graduate of the Medical College of Ohio in 1866.

Dr. William Thompson of Little Rock, Ark., died at his home, October 27, 1909, aged 70 years. He was a graduate of the University of Tennessee, in 1856, and was a member of the Pulaski County Medical Society and the Arkansas Medical Society

Dr. Frank C. Bruce of Easthampton, Mass., died October 31, 1909, aged 49 years. He was a graduate of the University of Vermont, in 1881, and was a member of his County and State Medical Society and the American Medical Association. Dr. Bruce was much interested in educational matters, having for many years held the position of chairman of the Easthampton school board.

Dr. Charles H. Burnham of Jefferson, N. H., died at his home, November 4, 1909, aged 66 years. Dr. Burnham was a graduate of the Medical School of Maine, in 1866, and had practised in Jefferson for over forty years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HARVEIAN ORATION—PROFESSOR OSLER AT THE LONDON HOSPITAL—SHORTCOMINGS OF THE UNIVERSITY—DR. WEST'S ADDRESS ON TEACHING IN THE WARDS—DISCUSSION AT THERAPEUTIC SECTION ON SAME—RED CROSS SOCIETY AND HOSPITAL FUNDS—OBITUARY.

London, October 22, 1909.

The Harveian Oration at the Royal College of Physicians was delivered on Monday by Dr. G. H. Savage. He began by remarking that it might be taken for granted that medical men knew all about Harvey, yet he found himself profoundly ignorant of the real man and his life work when he began to formulate his ideas on the subject. That Harvey lived in the disturbed times of Charles I., Cromwell, and Charles II., and that he first recognized the truth about the circulation, was well known, and there was little more to add to the story. He had himself nothing new and so would consider the man in relation to his times before other matters which might represent his injunction to seek for truth by unbiased research. He would not attempt to trace the evolution of Harvey's great discovery, as his predecessors had done. The time was ripe for that discovery, and many had nearly reached the goal. But no one had established the facts, no one had brought the power of examination to justify his belief. Comparing Harvey with some of his contemporaries who had not his special gifts, showed how different he was from his surroundings, making him come so unexpectedly as to resemble, as it were, a comet, unlike any other star in the firmament. In Harvey's time belief in witchcraft was strong and both he and Sir Thomas Browne were concerned in trials of witches, Harvey taking the more lenient view of the matter. The Herbalists at that time taught botany and materia medica and few things were more interesting than their quaint writings. Human anatomy was taught, but the credulity of writers on natural history was seen in their descriptions of animals. Harvey's guiding principle was observation as the base on which to build for the discovery of truth. Nature was, he held, the best interpreter of her own secrets. The orator then passed to his own specialty, remarking that Harvey had been more attracted to the material side of anatomy than to philosophy and mental disease, although he must have been brought into contact with the insane, for Bedlam was near his house, and his work at St. Bartholomew's. Psychology was not much in his line, and even now the seniors of the profession hardly regard it as offering a reward for a life's devotion to it. Yet the fact that already mathematical formulæ were being applied to experiments on the senses indicated that movement was taking place in that direction. The investigation of hypnotism, Dr. Savage thought, should not be ignored in England while other nations were carefully studying the physiology and therapeutic value of this influence. After the oration the president, Sir D. Powell, presented the several medals of the college to those to whom they had been awarded.

Professor Osler opened on the 15th inst. the three new laboratories of the London Hospital College for physiology, chemistry, and physics, respectively. They have cost about £8,000 and have accommodation for 120 students. There are no endowments of this college, but it is hoped that an appeal now being made for £100,000 will have a satisfactory response. Prof. Osler said it was a nice thing to see such a beau-

tiful group of laboratories in connection with a hospital, for they were the foundation stones on which its work rested. Many thought students might stay too long in the laboratories. He said they could not; they ought at least to stay long enough to get laboratory methods thoroughly engrained into their medical constitutions and carry them through life. He advised every student to take up a small piece of research work. To any who said that won't help in examinations he said take no thought for them. Besides, nowadays they were getting a group of very intelligent examiners. The students laughed heartily and the professor went on to denounce the scandalous injustice that the London University, so-called, does not give the London student the chance of obtaining a good, honest, ordinary M.D., and he advised the students to organize and agitate. The university, he said, had failed, so had the conjoint board. Now have a combination of London students, he said, and you will soon have what you need. The principal is here, the Vice-Chancellor is here, he continued, and I would not let them go if I were you until they have promised you shall be able to get a good M.D. At the conclusion of Prof. Osler's speech the Vice-Chancellor rose and said he would take courage and consider this matter, though he could not admit that the university had failed. Still he fully agreed there was something rotten in the State of Denmark, but no definite proposals had been sent to the Senate and perhaps that was where the blame lay. He agreed that they must organize.

Prof. Osler afterwards delivered his first "Schorstein" Lecture, which, as I told you, has been established in memory of the late Dr. Schorstein. The subject on this occasion was "Syphilis and Aneurysm from a Clinical Point of View."

Dr. Samuel West is president of the Medical Society of London this year and he opened the session with a very practical address, in which he protested against the cramming of students which at present prevails. To-day the student was largely spoon-fed, but predigested food was injurious to an animal's vigor; in rushing from one subject to another he had no time for digesting, and if it were not for his splendid powers of forgetting, which he shared with other men, the curriculum would ruin his constitution. So much time was spent in preliminaries none was left for the real practical work. Every one of the preliminary subjects must be pruned and the nonessential parts ruthlessly cut away. Pathology might be studied in the wards as well as in the laboratory. The theories of the pathologist based on the study of animals could not be applied to man until tested in the wards. To call treatment based on laboratory experiments rational and that based on clinical experience empirical implied a difference which did not exist. Treatment of symptoms was often disparaged, but if a disease could not be cured the patient might often be relieved. Symptoms were disorders of function caused by disease. Recently the bacteriologists had brought forward antitoxic sera and vaccines and their value was sometimes most striking, but at other times they failed. It was often said they could do no harm. It would indeed be strange if remedies so powerful for good could never do any harm. It would be unwise to let the enthusiastic bacteriologist run loose in the wards without the control of the clinician; it would, he held, be risky to science and to the patient also.

It is interesting to connote with the foregoing a discussion at the Therapeutic Section of the Royal on teaching in the wards. Sir Clifford Allbutt opened this by saying medical men must be pioneers; they could not afford to wait for the pharmacologists, but might advantageously watch them. Much of our knowledge was empirical, the knowledge of experience. He gave three examples of treatment originally derived from folklore, but which stood the test of modern research. They were digitalis, vaccination, which had wonderfully expanded in unanticipated directions, and poultices, which Bier had shown to be fundamentally reasonable, after they had been for a long time neglected and even regarded contemptously. The student ought to be taught that, quite apart from pharmacological evidence, there was a large amount of empirical knowledge of no little service; he should be told of remedies proved to be useful by clinical experience, whether they could be scientifically explained or not. He must also be told that he would have to do with living beings. He must be no skeptic or he would endanger his own resourcefulness; he should be given a clear idea of the vis medicatrix natural, warned against the overuse of drugs, and shown how dependent therapeutics is on prognosis.

Prof. Osler described the methods at Johns Hopkins University. Dr. Sainsbury advised teaching the history of therapeutics. Dr. Calvert deplored the neglect of incompatability and the simpler practical methods adopted in the wards. Dr. R. Hutchinson was for teaching diagnosis rather than pharmacology and the main lines of treatment which were generally employed in well-known diseases. Prof. Dixon dwelt on the importance of pharmacology and of accuracy in employing alkaloids and other potent remedies. Dr. Beddard said therapeutics could not be taught completely in the wards. Sir Dyce Duckworth urged the necessity of giving some practical instruction in the wards as to many duties often left to nurses. Dr. Hackney thought students might be taught how to manage a general practice.

Yesterday a meeting was held at the Mansion House to promote interest in the League of Mercy. It was explained that the objects of the organization were to provide a means whereby the poor might contribute small sums to the hospitals. Some, through their employers, gave a penny a month, but two-thirds of the population gave nothing. Still, during the ten years of its existence, the league had raised a sum of £120,000. In 1908 it gave £19,000 to King Edward's Hospital Fund. One of the speakers at the meeting expressed the hope the poorer citizens would contribute half a million shillings to help.

King Edward's Hospital Fund has come into a sum of £4,775 from the proceeds of the Franco-British Exhibition, now closed.

Hospital Saturday Fund was observed for the thirty-sixth year in succession last Saturday.

The British Red Cross Society has decided to form a London branch in connection with the Territorial County Associations and its scheme for voluntary aid for the sick and wounded and the St. John's Ambulance Association.

Sir Arthur Mitchell, K.C.B., died on the 12th inst. in his eighty-fourth year. He devoted his life to questions concerning lunacy. On the passing of the Lunacy Act of 1857 he was appointed a Deputy Commissioner and in 1870 was made full Commissioner. Ever since he has been concerned with all legislation as to the insane and received many honors, including the presidency of the Scottish Metereological Society, professorship at the Academy, the Hon. LL.D. of Edinburgh, Hon. F.R.C.P. Dublin. He had a great reputation as an antiquarian and as an archeologist, and wrote and lectured on those subjects as well as those relating to lunacy.

Dr. Rob. Lindsay, late A.M.D., died on the 15th inst. He entered the service in 1858 and retired in 1874. He was M.A., M.D. Aberd. and F.R.C.S. Ed. and wrote on malaria, etc.

Dr. Jas. Irvine Menzies died on the 17th inst., aged seventy-five. A Bart's man, he qualified in 1859 and had been retired for some time.

Dr. John Herbert Wells died on the 16th in his thirtieth year.

CONSUMPTION CURES.

To the Editor of the Medical Record:

Sir:—There appears to be a characteristic and almost unfailing connection between illiteracy and quackery. Some time ago I received a letter from a medical gentleman who claimed to have solved the tuberculosis problem, saying that he had received a letter of inquiry from one of my patients concerning his special methods of treatment, and asking whether it would not be profitable for me to apply the remedies according to the "inter-venious method." Polite reply was returned that, being wholly unfamiliar with the method indicated, I should have to decline the service.

A reputable man of large experience who had abundant opportunities for investigation assured me that the "cure" consisted of injections of warm salt solution into the veins of the arm. It was, in a sense, an operation by a special method, for which, of course, a large sum of money might, with some show of reason, be exacted.

"Cancer cures" seem to be on the decline. I suppose that the next generation will be educated in various methods for the eradication of tuberculosis.

Howard Crutcher, M.D.

Roswell, New Mexico.

THE WAR ON ADENOIDS AND TONSILS BY THE NEW YORK BOARD OF HEALTH.

To the Editor of the Medical Record:

Sir:—The Board of Health is conducting a veritable war against hypertrophied tonsils and adenoids. Children of school age are coming in a stream every day to the dispensaries and offices of private physicians to have their tonsils and adenoids removed. They are compelled to do it by the medical school inspectors. No one can deny that great credit is due the Board of Health for this efficient work, because, in removing early the adenoid growths and hypertrophied tonsils, we remove the probable cause of future complications of various kinds, such as a catarrhal condition of the Eustachian tube, otitis media, swollen glands of the neck, hindrance of respiration and circulation, a general slowing down of the mental and bodily development of the child, etc. Of course, nobody is perfect, and very frequently the medical school inspectors send children whose throats and noses are in perfect condition. I have seen many cases like this in Dr. Freudenthal's clinic for nose and throat at the Beth Israel Hospital. But this does not mean that the school inspectors do not attend to their duties right. On the contrary, it proves that they are anxious to do their full duty and are sending every doubtful and suspicious case to the specialist and hospitals. As an illustration of the great importance of early attendance upon adenoids and tonsil cases, I will relate the following case, which is characteristic of a good many others: A boy, about five years of age, was brought to my office by his mother, some time ago. The boy had a general swelling of the glands of the neck, a foul discharge from the nose, impaired breathing, a temperature of 101.5° F., a slight discharge from both ears, was in a drowsy condition, could hardly breathe. The examination of the throat showed slightly hypertrophied tonsils and a distinct adenoid hypertrophy. The mother told me that the child had been sick for a year, and during that time the family physician prescribed nothing but a nasal wash. I immediately removed the adenoid growths, which filled a good part of the nasopharynx. Within a few days all the symptoms disappeared. The temperature came down to normal, the glandular swelling of the neck disappeared entirely, breathing and respiration became normal, and soon the child was discharged cured.

Julius Solow, M.D.
78 McKibben Street, Brooklyn, New York.

Progress of Medical Science.

Boston and Medical Surgical Journal, October 28, 1909.

The Opsonic Treatment of Pyorrhœa Alveolaris.—T. C. Beebe, Jr., says that underlying all the various conditions which contribute to the onset and progress of this malady, there is a deficiency in the normal protective substances in the blood. As soon as the blood is stimulated to perform new protective substances there is an immediate improvement in the patient's local and general condition. The author reports a series of seventeen cases. In six the culture was practically one of pure pneumococcus. In all the others there was a slight admixture of staphyococci with the pneumococcus. In but one case had there been any sign of renal disease or diabetes. Two had had gastrointestinal disease, two were rheumatic, while in four there was a precedent history of Riggs' disease. In all the gums receded. In eleven pus could be expressed from the gums around the teeth. No *Spirochætæ refringentes* were found in any cases. Four had no loose teeth at the time, but two of these had lost teeth previously. The general results of the opsonic treatment were satisfactory. In some instances loose teeth became firmer. The author observes that in order to get the best results the opsonic treatment must be combined with most careful and thorough treatment. Nature must be assisted by the removal of calcareous deposits, loose teeth must be fastened in the best way possible, and malpositions should be corrected.

Relaxed Knees in Children.—M. H. Rogers says that the children are brought to the doctor because they cannot walk or run as fast as most children. They become easily tired and want to be carried. They are clumsy in running and awkward in walk, showing a tendency to fall. If the symptoms are more severe there is a feeling of discomfort, even of actual pain referred to the legs, especially the knees. At night when the children are first put to bed there may be restlessness and sometimes a crying out simulating the night cry of joint disease. The condition of the knees is the most prominent feature. When the child is at rest there is a slight knock knee, and one or both knees are in a hyperextended position. One knee may be held in a normal position, but when the weight of the body is shifted, that knee joint will spring backward. The position of the feet is more pronated than normal, and the scaphoid is prominent and low. In most of the cases, especially in a well-marked case, there is a good deal of lordosis of the lumbar spine and a prominent abdomen, and the shoulders are generally rounded and the head is held forward. The spinal muscles are prominent and sometimes held in spasm. When the child is lying down the knock knee can be corrected in cases where there are no rachitic changes of the epiphysis. There is a very appreciable laxity of the knee joint, and in all cases it is possible to obtain lateral motion. This is the most prominent feature in this condition. Sometimes we see a child presenting such a picture who also toes in, especially on walking. It is rather difficult to explain why there should be toeing-in and pronation at the same time, because one represents a certain degree of varus and the other valgus. This condition is seen in children who have had a good deal of joint relaxation for some time, and probably means that the child is trying to correct its balance and toes in to obtain a stronger standing position. In carrying out our treatment for relaxed joints, sometimes this toe-in is increased, but later will take care of itself. In the treatment of this condition there is no need of apparatus unless the knock knee is very pronounced. The pronation of the feet is best treated by raising the inside edge of the heel. To prevent hyperextension of the knees, spring-heeled shoes are worn, and by putting on heels from ½ to 1 inch in height the child is tipped forward and compelled to stand slightly flexed.

New York Medical Journal, October 30, 1909.

Gastric Ulcer in the Young.—A. Jacobi refers to the bibliography of this subject and then passes on to a general description of the subject. As causes he cites prenatal disposition, thrombosis of the umbilical vein and its small branches, local embolisms on the gastric wall, burns and septicemia, spasm caused by hyperacidity, local injuries, and infectious fevers. Symptoms are pain, vomiting, and hemorrhage. Statistics as to mortality vary from 2.4 to 50 per cent, according to the various authors. Treatment is to be conducted along the same lines as for adults. A diseased organ must not work. It must rest. An acute case requires rest in bed, morphine in proper dosage may be necessary. Hemorrhages require starvation and ice on the stomach, morphine by syringe or by mouth. Adrenalin is useless when swallowed. Lead and ergot have not been satisfactory to the author. Gelatine has been recommended, but its bulk is an objection. The author has seen good effects from ligation of the venous circulation in the lower extremities, chronic cases call for strict dietetic regulations. Milk should be taken with a spoon so as not to coagulate. Medicines are required to keep the stomach alkaline. The best preparation of bismuth is the subcarbonate. The author cannot advise instrumental treatment. Silver nitrate is a good remedy in relapsing and protracted cases. After treatment may require a long time. Warm applications may relieve local pain.

The Clinical and Pathological Significance of Bacteremia in Suppurative Otitis.—A. B. Duel and J. Wright report a series of sixteen cases of bacteremia out of sixty-seven cases examined. Four patients had definite clinical signs of septic sinus thrombosis for which jugular ligation and excision, and opening of the sigmoid sinus was performed (two with demonstration of clot; two without, on account of violent hemorrhage; recovery in all). One patient had acute suppurative labyrinthitis and acute diffuse leptomeningitis. One patient had acute purulent otitis without mastoid involvement. Two patients from the throat clinic had frontal sinusitis; one of these cases was complicated by meningitis. The remaining nine cases were those of mastoiditis without complications, each of these patients ran an uneventful course after operation. Streptococci were present in fourteen of the cases, pneumococci in two. It is significant that streptococcemia was present in all of the patients presenting clinical symptoms of sinus thrombosis, and in the case of diffuse leptomeningitis; however, it is none the less significant, from another point of view, that in nine patients without any alarming symptoms of further complications seven had streptococci and two pneumococci in the blood. It seems

perfectly evident that a bacteriemia occurring in the course of a purulent otitis can by no means be considered sufficient cause for invasion of the sinus in the absence of other definite clinical symptoms.

Intravenous Injections of Mercury.—W. F. Brenner reports a series of nearly ten thousand intravenous injections given for their antisyphilitic action. Over four hundred different patients were treated. A simple phlebitis followed in 208 instances, but rarely lasted over from four to seven days. An obliterating endophlebitis followed 48 of the injections. Obliteration did not always occur at the site of injection. The severest case of phlebitis followed an injection of mercuric lactate, supposed to be one of the least irritating of the mercury salts. The author has had no case of embolism in his own practice nor can he find recorded an authentic case in the practice of others. No renal complications have been observed except in three cases. Occasionally there have followed the injections a severe intestinal tenesmus, and a simple or even a bloody diarrhea. The smallest dose of the drug that ever produced a bloody diarrhea was three-twentieths of a grain of the bichloride given in the course of 20 hours. The exact curative value of the treatment is difficult to outline because of the limited number of patients treated, the lack of sufficient time for observation and the insincerity and migratory character of many of the patients treated. The previous reference to a full term treatment meant the administration of an intravenous course every two to four months over a period of one and one-half to two and one-half years, the intervals between these courses being covered by the intramuscular use of some insoluble salt of mercury or the administration of medicine by mouth. Rest from treatment, the use of iodides or tonics, was controlled by the same causes which would be competent for cases under some other method of medication. Of the twenty-two patients who completed this prescribed course (treatments finished before February, 1908) only one has shown a recurrence of his disease. The case showing the longest period of freedom from any syphilitic signs since the completion of a full term treatment, stopped all medication over five years ago. Those patients taking only one intravenous course and then neglecting further treatment showed that the shortest period of freedom from symptoms was about nine weeks and the longest over five years. Although unable to draw any positive conclusions as to the exact curative value of the intravenous medication, it can, however, be emphatically stated that a single course of such injections carries more effective therapeutic value than can be obtained in the same time from any other method of medication. When active syphilis is the factor to be considered they always will produce quick and favorable results.

A New Treatment of Locomotor Ataxia Based on a New Theory of the Disease.—A. Heym says that the destruction of nerve tissue in this disease is due to the toxins not only circulating in the blood but also contained in all the other bodily fluids. The ganglion cells of the spinal ganglia are the trophic centers of the sensory peripheral nerves and of the posterior roots and their prolongations. The ganglia are in direct communication with the subarachnoid space by means of the lymph paths and a part of the cerebrospinal fluid flows off that way. Hence, from the beginning of the disease the nerve tissue of the ganglia is exposed to the toxins of the fluid named. The ganglia are changed first in their functions and later in their structure. The functional change lowers the resistance of the nerve fibers. The motor nerves have the power to resist longer than the sensory ones, because their trophic centers are located in the spinal cord itself, but at the end we often find a degeneration of the motor nerves and a general atrophy of the muscles. In a similar way originate the lesions of the cranial nerves. In treatment these toxins must be neutralized where they are most abundant. The author has employed the arsenical preparation known as cacodylate, containing 0.05 in 1 c.c., the technique of the injection being the same as for lumbar puncture. He has a series of twelve cases to report. The neuralgic pains of the disease are not relieved by the injections but are relieved by the iodide given internally in saturated solution. The author hazards no statement as to how long good effects of the injections will continue after the latter have ceased.

Journal of the American Medical Association, October 23 and 30, 1909.

Cardiac Thrombosis.—F. Smithies reports the clinical and pathological findings in three cases of cardiac thrombosis treated in Professor Dock's clinic at the University Hospital, Ann Arbor. Two patients were males, one female, and in one case the diagnosis was made antemortem. He defines the term cardiac thrombus as "a solid or partly solid structure, primarily formed from blood elements, which develops in one or more chambers of the heart during life. Such a mass may be attached to the cardiac wall by a more or less altered base, or may exist as a free foreign body within a heart cavity. When cardiac thrombi are measured by this standard they are uncommon post-mortem findings. This applies especially to those of the free, or 'ball' variety." These formations are now considered as due to some damage done to the endocardium, either infectious, toxic, or mechanical, together with the increase of hemagglutinins in the blood and slowing of the blood stream. These are the essential factors. With the exception of influenza, tuberculosis, and perhaps rheumatism and syphilis, cardiac thrombi are uncommon products of infectious disease. They sometimes occur in the cachexias of cancer, malaria, etc. It is possible for them to arise from any part of the endocardium, even the valves, though the majority arise from the septum, the foramen ovale, and the auricular appendage. The symptomatology varies with the location and the symptoms are those of impeded circulation. An acurate diagnosis is not practicable, but some authorities claim that it should be suspected when in the course of a cardiac lesion the signs become anomalous and confused with practical loss of the clinical picture of either definite cardiac lesion or typical cardiac inadequacy. The reasons given by the patients, whose cases are here detailed, for entering the hospital, were shortness of breath, pain about the heart and stomach, general weakness, cough, cyanosis, edema, and palpitation. In discussing the special points of interest in these cases, Smithies calls particular attention to certain features of one case which seemed to indicate to him that the ante-mortem diagnosis of certain heart thrombi is not altogether impossible if the physical signs are carefully observed and reported. Of these physical signs he lays special stress on atypical peripheral vascular manifestations with the more or less characteristic auscultation and percussion signs in the heart itself. The manifestations of embolic process should always furnish significant information. These were constant in the cases here recorded. When the diagnosis appears likely, there can be little said as regards treatment. The suspicion of a thrombus makes a bad prognosis and certainly limits the prospect of doing any good with drugs in a heart whose compensation appears to be failing.

Eclampsia.—J. E. Welch says regarding the pathology of eclampsia, the typical picture accepted by most of those familiar with the subject consists in hemorrhages in and about the portal spaces, thrombi in vessels of the liver, and giant cell emboli in other organs. There changes found in post mortems of pregnant or postpartum women are considered by many as justifying the diagnosis of eclampsia, and with these changes in mind the clinician will sometimes make the diagnosis of eclampsia without convulsions. Obstetricians have for some years been calling a symptom complex characterized mainly by headache, visual disturbances, nausea, vomiting, delirium, and coma, with or without edema, the toxemia of pregnancy. This syndrome which seems to be due to a more or less profound systemic poisoning has been considered as a different disorder from eclampisia because of the usual absence of convulsions. Instead of hemorrhages about the portal spaces of eclampsia there was found in these cases extensive necroses which, in their early stages limited to the liver lobule, later invaded the remaining part of the lobule and produced the picture of acute yellow atrophy of the liver. A difference of opinion has arisen among pathologists as to the independence of these two disorders—toxemia and eclampsia—some holding that they are only different manifestations of the same general condition. The author reports several cases of these two classes and gives his views as to the origin of the different symptoms. He sums up his general conclusions as follows: "1. The liver lesions in eclampsia are not uniform. Pregnant or postpartum women dying from convulsions may have hemorrhages, central necrosis, general autolysis, or cloudy swelling in the liver. 2. The liver lesions in toxemia of pregnancy are not uniform. They may be either hemorrhagic or central necroses, both of which are found in eclampsia. 3. The hemorrhagic lesions are produced by liver and placental cell emboli, thrombi formed from blood plates and fused red blood cells, and by a solution of vascular endothelium. Heightened blood pressure increases the extent of the hemorrhages. 4. The agent producing the hemolysis and general cell destruction is probably an enzyme."

Placenta Prævia.—A. Stein disagrees with any whole-

sale condemnation of the use of vaginal section in placenta prævia. When there is central implantation of the placenta, it no doubt is dangerous, but in his opinion there are certain cases in which it is justifiable because it enables the obstetrician to become master of the situation quickly and safely. These are those cases of lateral placenta prævia in which we are forced to rapid interference and in which we are sure beforehand that we can avoid the placental insertion. He reports a case with extensive hemorrhage, in which this method was employed (Doderlein's modification of Duhrssen's method) with success, as regards the saving of the mother though the child was lost. He was astonished at the small amount of hemorrhage. In this case he had to do a quick and at the same time safe operation and other methods were out of the question, though the result was not an ideal one so far as the baby was concerned. This operation enables one to open the uterus enough to permit delivery in the normal passage without loss of time in a clean cut surgical way and at any moment during pregnancy or labor.

Quinine and Urea Anesthesia.—A. F. Hertzler, R. D. Brewster, and F. B. Rogers report the results of their treatment and experimental studies with quinine and urea hydrochloride anesthesia. They have been using the drug instead of cocaine in all the cases of local anesthesia to their complete satisfaction. They found that a perfect anesthesia is obtained which lasts from four to five hours. Disturbances in skin union sometimes occurred, however, making the wound slower to heal than when cocaine was used. There was marked induration and thickening, and Hertzler undertook to determine the cause, and found that instead of being cellular it was due to a purely fibrinous exudate. To what extent this fibrinous exudate is subsequently converted into fibrous tissue is not definitely determined, but apparently nearly all is absorbed. With the 0.25 per cent. solution this induration did not occur to any notable degree, however, and this seems to be therefore the strength advisable to use in operations where speedy primary union of the skin is desirable and where anesthesia lasting more than several hours is desired. In operations in which delayed action is unobjectionable, the stronger solutions are those of choice. He gives a number of disorders where this anesthetic has been found satisfactory, such as drainage of the gall-bladder and of appendiceal abscesses, exploratory laparotomies, hernias, castrations, varicocele, and hydrocele operations, etc., and specially recommends it in anal operations and tonsillectomies. The advantages over cocaine are the absolute safety and duration of anesthesia.

Antimeningitis Serum.—S. Flexner says that it is now three years since the antimeningitis serum has been employed therapeutically in this country, and within that period its employment has extended into Great Britain, France, and Germany. Heretofore, the epidemics in which it has been used have been mostly on the down-hill grade at the time, and a fair test of its efficiency during the period of the height of the incipient period of an epidemic when the mortality is at its height had not been made until the present outbreak in France. He gives tables showing the results of analysis of 712 cases of epidemic cerebrospinal meningitis which had been treated with the antimeningitis serum, the one showing the mortality according to age groups, and the other according to day of injection. These tablets are instructive as showing the importance of early injections of the serum, especially in the early years of life when the mortality is greatest. Flexner hopes to consider them in more detail in the near future. He emphasizes a point to which he has previously referred, namely, the importance of experience with the serum in securing the best results from it. The tables also show an increased mortality in the two highest age periods, approximating to that of infancy, which is not wholly accounted for. The explanations that suggest themselves are, that among older individuals there tends to be a large number of very severe, rapidly fatal cases, or that older persons are less subject to the beneficial action of the serum. He also touches on the point that the study of certain groups of cases coming under one observer indicates that the diagnosis can sometimes be made before the usual symptoms of meningeal irritation appear. The cerebrospinal fluid removed by exploratory lumbar puncture reveals the presence of the meningococcus and an immediate injection of the serum either abruptly terminates the case or the disease runs a relatively mild course.

Indicanuria.—Judson Daland says indicanuria may be mild or severe, acute, chronic, or recurrent and occurs as an independent affection or as a complication of other conditions. Its presence is significant of the absorption of products of putrefaction, usually in the intestines, but occasionally in other parts of the body. It may be absent during protein decomposition if absorption is prevented, and it is conceivable that intestinal toxemia may occur without indicanuria. The severe forms of intestinal toxemia simulate cholera and may cause death within a week. No exact knowledge exists as to the precise manner in which the body protects itself from the poisons produced during protein decomposition, but it is believed that the liver cells and intestinal mucosa have some such function. Clinically, indicanuria is more likely when the hepatic function is disturbed than when it is not. It not infrequently exists without symptoms, but there is no certainty that it is then harmless. The conditions that favor it are numerous. The importance of morbid conditions in the teeth, mouth, nose, etc., are too little recognized. Morbid conditions of the intestine and stomach, hernia, ileus, appendicitis, all produce favoring conditions for its occurrence. The author has emphasized elsewhere the importance of the recognition of indicanuria in typhoid. Constipation may exist without indicanuria, but it is exceptional. Acute attacks of toxemia are frequently associated with dark-colored, hyperacid urine of high specific gravity and indicanuria, and as the toxemia increases in frequency and intensity or becomes chronic with exacerbations, the long-continued irritation of the kidneys may lead to chronic interstitial and parenchymatous nephritis. The circulation in the blood of the derivatives of putrefaction derived from the intestines causes varying degrees of anemia which in extreme cases may simulate pernicious anemia. The toxins may also produce arteriosclerosis. The relationship of indicanuria to the nervous system is varied and most interesting. Neuroretinitis, neuralgias, pains in various parts of the body simulating rheumatism and gout, headache usually frontal, though sometimes in the vertex or occiput. The duration varies from a few hours to a few days, and it may be kept up thus for years with the cause unrecognized. Intestinal toxemia is as frequent a cause of headache as are refraction errors. Persistent insomnia has also been observed, and chronic intestinal toxemia may induce or complicate cases of neurasthenia. Benefit from a milk diet in neurasthenia is not improbably the result of the suppression of an intestinal toxemia. Indicanuria is a common complication of the various forms of insanity and has been associated with epileptiform convulsions. It has hindered the favorable course of many cases of tuberculosis, and diagnosis of such complication is essential in that disease. Catarrhal inflammations of the respiratory tract are aggravated by it, and skin diseases have been observed in connection with this condition. It is a common disease in itself and a frequent complication with other diseases, and its removal is very frequently followed by marked amelioration or disappearance of many distressing symptoms.

Intestinal Antiseptics and Peptic Digestion.—A. Heineberg and G. Bachmann have studied the effects of a number of the commonly used intestinal antiseptics, benzoic, boric, and salicylic acids, beta-naphthol, creosote, phenol, resorcinol, sodium phenolsulphon, sodium sulphite, and thymol, as regards their action. They do not believe that the use of the U. S. P. process and its modifications employed in this study at first enables us to form accurate conclusions, either as to the digestive power of pepsin or to the effect which other substances may have on peptic digestion, even *in vitro*. They therefore adopted what they consider a more accurate method, consisting in the estimation of the amount of peptone and allied products formed at the end of digestion by determining their nitrogen content according to the Kjeldahl method as recommended by Katz. Their conclusions are summed up as follows: "1. Intestinal antiseptics interfere with peptic digestion *in vitro*. 2. Beta-naphthol, salicylic acid, sodium sulphite and thymol are the most active in retarding digestion. 3. Boric acid and resorcinol are the least active. 4. The uniformity in the results of our experiments would seem to warrant the inference that intestinal antiseptics interfere with digestion in the stomach and probably in the intestine."

Hemolysis in Cancer.—O. P. Johnstone and C. H. Canning have studied the hemolysis reactions in tuberculosis and in malignant growths, with the object of determining their value as aids to early diagnosis. They found that only the advanced or decidedly active cases of tuberculosis gave reversed hemolysis, the others being negative. In carcinoma cases the positive reactions were in a great majority, and several of the cases giving negative ones showed slight hemolysis after from 48 to 78 hours. In carcinoma of the rectum, two cases out of three gave a negative reaction, but these two were not examined microscopically, so a clinical diagnosis was not verified. In

nine cases of sarcoma of various types, all gave more or less positive reactions, but less pronounced than the carcinoma cases, but with one exception they were all small or of moderate size. One patient who had been operated on and treated with Coley's fluid gave a negative reaction six months after the operation. There has been no recurrence one year after operation. In one of the nine cases the sarcoma was incompletely removed, and treatment with Coley's fluid employed. The final examination showed but a very slight hemolysis. Two patients with endothelioma were examined, the reaction was positive in each. No benign tumors showed hemolysis. A considerable number of patients suffering from various diseased conditions were examined and the results tabulated, together with those from eighty-five normal individuals. The technique employed was that of Crile, with very few minor variations. The authors' conclusions are given as follows: "1. The hemolysis reaction appears to be of decided value in the diagnosis of malignant neoplasms. Negative results do not rule out malignancy, but speak strongly against it. 2. The reversed hemolysis appears to offer valuable information with regard to the extent and activity of the tuberculosis lesion. 3. Several examinations should be made in doubtful cases. 4. The reaction does not appear to occur in other conditions that would lessen its value in the diagnosis of malignancy."

The Lancet, October 23, 1909.

Fatal Case of Septicemia Illustrating an Important Fact with Regard to the Lymphatics of the Upper Limb.—W. B. Brownlie's patient was a farm laborer with a painful swelling below the left clavicle in the infraclavicular region. It was hard, did not fluctuate, and showed considerable edema at the margins. Axillary glands were not enlarged. There was a history of a suppuration about one of the finger nails two weeks before. Diagnosis was made of acute lymphangitis of the costocoracoid glands following paronychia. The subclavicular swelling spread and the patient developed symptoms of general infection. The swelling became covered with vesicles containing blood-stained serum and was opened up. A deep incision was made between the pectoralis major and the deltoid, but no pus was found. The tissues were gangrenous, the patient, not feeling the incision, and cultures showed streptococci. In two or three days the patient had other rigors, and a new swelling appeared behind the angle of the jaw on the right side, probably a thrombosis of the internal jugular vein. He died at the end of three days, the mental condition being clear to the end. The anatomical point involved in this case is that, while drainage from the fingers naturally goes to the axilla, some of the lymphatics from the backs of the fingers go at times along with the cephalic vein to the costocoracoid glands in the infraclavicular fossa. This holds true with reference to the posterior aspect of the thumb, forefinger, and radial side of the middle finger. This route is of more danger to the patient because of the closer proximity of the costocoracoid glands to the large veins of the neck, and they are also a bit nearer to the thoracic duct.

The Importance of the Early Recognition of Tuberculous Mediastinal Glands in Children.—The general clinical cause of such cases is detailed by J. Allen, who dwells on the importance of early recognition so that proper treatment may be begun before the lung becomes involved. Great attention should be paid to afternoon fever, anemia, steady loss of weight, etc., and especially a spasmodic cough, to the significance of which the author attaches much attention. It is very similar to the cough of pertussis, and if it continues after the subsidence of an attack of the latter disease it is probably due to enlargement of the bronchial glands. Bronchiectasis may give a similar cough, but this condition is unusual in children. In early enlargement of the bronchial glands physical signs are wanting, but this might be expected, as the glands are small and deeply situated. If a gland causes constriction of a man's bronchus definite signs follow. Dullness, in any event, may be found under the manubrium, extending outward toward the pulmonary apices and downward toward the cardiac apex. One of the earliest signs of main bronchial constriction is diminution of vocal fremitus. Later the vocal resonance is impaired, breath sounds are feeble, and chest expansion defective. If the pressure is sufficient to prevent the entrance of air or if one of these large tubes has been plugged up by a caseous mass, there is absence of respiratory murmur over a single lobe or even entire lung. The Grancher sign is very variable and cannot be relied on. The tuberculin test controlled by the opsonic index is of much value.

Chronic Glanders in Man with Reference to an Unusual Type Affecting the Upper Respiratory Tract.—O. L. Addison and G. S. Helt report the case of a carman complaining of sore throat and presenting extensive ulceration of the palate and pharynx. One year before he had been seized with violent cramps in the legs and headache, stating that a horse he had been driving had had a "watery discharge from his nose and lumps under his jaw." An abscess developed on his forearm, but the pus from it was sterile. The case was thought to be one of influenza with intramuscular abscess. He remained under observation for several months without much benefit. At that time there was extensive ulceration of the nasopharynx and tonsils, with loss of the right anterior faucial pillar. Liquids taken returned through the nose. He again entered the hospital, having ulcerations in various areas of his throat and nose and abscesses on the face. Later cultures were made of the pus and revealed the bacillus of glanders. Finally his lesions healed and he was discharged. In general the lesions resembled those of tertiary syphilis, but Wassermann's reaction was negative. Points to be considered in these cases are history, occupation, type of ulceration, temperature (the patient had a daily fever), presence or absence of undoubted signs of syphilis, and reaction to antisyphilitic treatment. Improvement in chronic glanders is said to have resulted from mercurial treatment. Injections of mallein have been followed by improvement, and the authors suggest that possibly good may result from vaccines.

British Medical Journal, October 23, 1909.

Rodent Ulcer Treated by Potassium Bichromate.—The patient of W. Gemmill was a woman of 82 years, who had a sore nose for two years. The ulcer ran from the nasion above to the border of the nasal bones below. Laterally, it approached to within one-quarter inch of the inner canthus of the left and to within three-eighths of the inner canthus of the right eye and covered most of the bony skeleton of the nose. It had an irregular border with an ulcerated center and caused no pain but a constant itching. A 10 per cent. watery solution of the acid was painted on night and morning for a few days and a marked inflammatory reaction set in in the surrounding tissues, the ulcer being protected by lint held in position by plaster strips. The application was then stopped for a while, boric acid ointment being used meantime. The ulcer soon took on a more healthy look and granulations were seen. The whole process was repeated twice more and the ulcer completely healed, a somewhat irregularly pitted scar being left. Two weeks later a small portion of the margin began to break down. This was checked by two more applications. The whole period of cure occupied three months.

The Diagnosis of Malignant Disease by Means of the Antitryptic Index.—By the antitryptic index is meant, says H. W. Bayly, the power of inhibiting tryptic digestion possessed by any given serum, compared with such inhibitory power possessed by a normal standard serum, in other words, the ratio of the powers possessed by different serums for neutralizing tryptic ferments. The author refers to the work along this line of various investigators and reports his own experiences in 30 cases of carcinomata in various parts of the body. Of these 26 showed a markedly raised index, the remaining 4 showed practically normal indices except one, which was subnormal. This case was a very advanced one of the antrum of Highmore and died before a second test could be made. If bacterial infection is present, this method cannot at the moment claim any great value, but in the absence of such infection, it is of very great value in affording a diagnosis between malignant disease and gastric and intestinal ulcers, aneurysms, nonmalignant, disease of the bladder, or nonmalignant conditions of the pelvis in women. The negative evidence afforded by a normal antitryptic index is also of very great value in excluding malignant disease.

Report on Cancer Research.—H. C. Ross and C. Macalister detail the results of their investigations by *in vitro* methods. Over a year ago they discovered in the blood of cancer patients a substance which, like the artificial excitant of methyl blue and atropine, excites ameboid movements in leucocytes, and they described how lymphocytes in the presence of both these excitants extruded what at the time were believed to be flagella. These observations suggested the advisability of instituting a combined clinical and pathological research upon the lines referred to in the present paper, especially since the study of cancerous tissues *in vitro* had thrown some light on the behavior and possibly also on the character of the cancer cell itself.

They summarize by saying that they have found a chemical substance which causes a remarkable train of events when it is absorbed by human lymphocytes in that it promotes first an excitation of ameboid movements, then reproduction, and finally death. When it is considered that this series of phenomena constitute two of the cardinal facts known about cancer, for the cause of cancer, whatever it may be, must be an excitant of cell reproduction which ultimately leads to the death of the individual, the inference may be drawn that this first event in cancer may be followed by the succeeding ones, reproduction and death, which are produced by this artificial substance under the microscope. In the body the rapidity of change is far less rapid and would probably be spread over several generations of cells. Methyl blue and atropine excite ameboid movements in leucocytes; so does the blood of a cancer patient. The same mixture will cause lymphocytes to extrude flagella with a particle of chromatin at their ends; so will the plasma of a cancer patient. The authors have shown that the extrusion of chromatin seems to be a phenomenon which appears in cancer cells and that cancer cells apparently produce something which aggravates the disease. This something may be chromatin. This substance may excite the three changes in the chain of events referred to. The promotor of the first of these or its excitant exists in the blood of cancer patients and to a greater extent in cancer juice. If chromatin or a derivative of it is the something which aggravates the disease, in order to produce a chain of events similar to that which has been observed in lymphocytes, it will have to aggravate the action of a substance resembling in effect that contained in the aniline dye which caused first reproduction and then death. It may also be noted that chromatin is a product of catabolism, which may predispose to the disease in persons over the age of forty years.

Berliner klinische Wochenschrift, October 11, 1909.

Chlamydozoa in Nongonorrheal Blenorrhea Neonatorum.—Halberstaedler and v. Prowazek give the name of chlamydozoa to the class of microorganisms which are found in the conjunctiva in trachoma, and have been known as "trachoma bodies." In reply to the recent statement that these so-called trachoma bodies were not specific for the disease, as they occurred in gonorrhea also, the authors undertook the present piece of work. Secretions and epithelium were examined from the urethra in 35 cases of acute and 20 of chronic gonorrhea. The bodies were found in none of these, nor in secretion from the cervix and urethra of 15 infected women. In a series of gonorrheal blenorrhea neonatarum, the results were also negative. On the other hand, the chlamydozoa were found in the secretions from the eyes of five other infants who had what appeared clinically to be ophthalmia neonatorum. Repeated smear and culture examinations of the secretions from these cases, however, failed to show the presence of gonococci. In two of the cases the mothers of the infants were examined, and in one instance the typical bodies were found in the epithelial cells of the urethra. From these findings the authors conclude that the chlamydozoa do not occur in gonorrheal ophthalmia, but that there is a nongonorrheal form of blenorrhea neonatorum due to these organisms, which is not identical with the "trachoma bodies," but both organisms belong to this one class of chlamydozoa.

Münchener medizinische Wochenschrift, October 12, 1909.

Light Treatment of Bone Tuberculosis.—Freund says that the ray and light treatment of bone caries deserves earnest consideration, and where a conservative treatment is to be carried out, should be given a trial. However, climatic-hygienic and surgical-orthopedic methods must not be neglected. It is certain that in the mountain country, where the weather is constantly good and rain never protracted, similar good results might be obtained if the medical profession would begin to appreciate the fact. For cloudy days, however, and for those unable to go to the mountains, *x*-ray and arc light treatments come in play. It is especially indicated to carry on these investigations particularly as the beneficial action of the radium and *x*-ray therapy, which is reported from all sides, may also appear in tuberculous manifestations of other organs, as peritonitis, cystitis, and phthisis.

Blister Produced by Hypnotism.—Heller and Schultz report a case in which a patient was put under the hypnotic influence and the suggestion made that his hand had been burned, but the burn would be painless. The hand was then bound in cotton. Five hours later, under repeated hypnosis, the bandage was removed, and a red, inflamed patch was found, in which was a blister 2.5 cm. x 1 cm. in size. Pricking the blister let out a few drops of a rapidly coagulating fluid which contained a few epithelial cells, but no leucocytes. The patient was then given the suggestion that the hand would heal very rapidly and he was awakened. The next day there was still definite reddening, though less marked, and the blister was more lax. Five days later the hand had healed, leaving a smooth scar. From this style of healing the authors believe that the process was not similar to a fictitious urticaria but was a true epithelial necrosis.

Vicarious Menstruation in the Form of Lip Hemorrhage.—Hauptmann reports the case of an eighteen-year-old, physically well developed and healthy girl who gave the following history: At fourteen she began every four weeks to have marked swelling of the lips with a sensation of prickling and drawing. The swelling was of a purple color from extravasated blood. It lasted three to four days and disappeared. At the age of fifteen menstruation began, but was not regular. When the normal menstruation did not appear the facial swelling came in its stead. The author personally observed the swelling of the lips on four successive monthly periods.

Geographical Distribution of Diabetes Mellitus.—Williamson says that diabetes varies greatly with location and race. In England the diabetes mortality is 9.6 per 100,000; Malta, 37.8; Bordeaux, 25.8; Berlin, 20; Paris, 17.6; Worcester, 27.3; Syracuse, 25.7; Boston, 17.9; New York, 17.4. The disease is very common in Bengal, Ceylon, Siam, Tunis, and Madeira. Jews are markedly disposed to the disease. In Pesth the mortality from diabetes is seven times as great among the Jews as among the Gentiles. The poor Chinese have very little of it; the rich Chinese much more. In Japan it is as frequent as in Europe. Negroes do not have it as frequently as whites; in Baltimore the mortality per 100,000 among negroes is 8; among whites, 16.3. The disease is increasing in certain countries. In England and Wales the mortality was in 1886, 5.9, in 1907, 9.7; in Paris in 1881, 5.8, in 1890, 13, in 1906, 17.6; in Copenhagen in 1885-9, 8, in 1906, 15.3; in Berlin in 1881-90, 4.3, in 1891-1900, 8.2, in 1905, 16, and in 1906, 20; in Victoria, Australia, in 1902, 3.8, and in 1907, 11. In most countries men are more prone to diabetes than women. In New Zealand, Scotland, Havana, Buenos Aires, and a few others, the women are in excess.

Deutsche medizinische Wochenschrift, October 14, 1909.

Salt-Free Diet for Diseases of the Urinary System During Pregnancy.—Oskar Jaeger has made a study of the effect of a salt-free diet in all of the cases in his obstetric clinic which showed symptoms of nephritis, eclampsia, pyelitis, and cystitis, from which he draws the following conclusions: A salt-free diet is not a cure-all by which every case of nephritis gravidarum can be healed or even improved. There are many more cases of severe pregnancy nephritis where this therapeutic method, as well as every other conservative treatment, fails, and in order to save the life of the mother a forced abortion is an absolute necessity. Experience has, however, shown that a systematic withdrawal of all salt, especially where combined with a decrease of the water intake, is frequently a most valuable therapeutic procedure, not only to reduce the edema of the nephritis of pregnancy, but also to improve markedly all the other symptoms of the disease. In the treatment of the pyelitis and cystitis of pregnancy, the salt-free diet may be used as a nonirritating diet in the place of milk with excellent results.

A Large Omental Cyst in a Boy.—Seefisch reports the case of a boy of four years of age who was brought to his clinic supposed to be suffering from tuberculous peritonitis with ascites. The child was extremely emaciated and anemic, with an enormous abdomen. The lungs were normal and the glands not enlarged. The urine was normal; the pulse small and rapid, the temperature normal. The abdomen presented the appearance of a high grade of ascites. There was fullness in the flanks and tympany near the navel. The fullness was movable, and fluctuation was marked. Operation, however, demonstrated an enormous cyst of the large omentum with thin, dark, bluish-red walls attached to the transverse colon by a pedicle the size of a pencil. Its capacity was from 2½ to 3 liters, and it contained much blood, which it was interesting to find, on microscopic examination, was quite normal. There was no increase of white cells in the fluid. The cyst wall was formed of infantile omental tissue, composed of small fat cells, between which lay loosely connected fibrillary connective tissue strands. The patient recovered. True cysts of the omentum, Seefisch declares, are very rare.

Book Reviews.

American Practice of Surgery. A Complete System of the Science and Art of Surgery, by Representative Surgeons of the United States and Canada. Editors: Joseph D. Bryant, M.D., LL.D.; Albert H. Buck, M.D., of New York City. Complete in Eight Volumes. Profusely Illustrated. Volume VI. New York: William Wood & Company, 1909.

This volume, of over 900 pages, is devoted entirely to regional surgery, and is therefore of special practical value. The several chapters are on: Prosthesis in Its Relation to Surgery of the Face, Mouth, Jaws, and Nasal and Laryngeal Cavities; Surgical Diseases and Wounds of the Nasal Cavities and Accessory Sinuses; Surgical Diseases and Wounds of the Mouth, Tongue, and Salivary Glands; Surgical Diseases and Wounds of the Neck; Surgical Diseases and Wounds of the Thyroid and Thymus; Surgery of the Thorax and Spinal Column; Surgical Diseases and Wounds of the Female Breast; Surgical Diseases and Wounds of the External Genitals and Vagina; Surgical Diseases and Wounds of the Male Genital Organs; Chancroid; Gonorrheal Urethritis; Surgical Diseases and Wounds of the Jaws.

The contributors are George E. Armstrong of Montreal, Franklin Green Balch of Boston, Joseph Colt Bloodgood of Baltimore, Hugh Cabot of Boston, Norman Bruce Carson of St. Louis, John M. Elder of Montreal, William Phillips Graves of Boston, Harris Payton Mosher of Boston, Harvey Gilmer Mudd of St. Louis, Francis J. Shepherd of Montreal, and Charles R. Turner of Philadelphia—all names which those who are acquainted with surgical literature will recognize as of men well fitted by special experience to deal authoritatively with the subjects assigned to them. The volume is quite lavishly illustrated with eleven colored plates and over six hundred text figures.

With the work now three-quarters completed one may safely pass judgment upon it as a whole; at least one may affirm that, if the two remaining volumes maintain the character of the six already published, the series will constitute the most exhaustive and indisputably the most authoritative treatise on the exercise and art of surgery which has ever been presented to English-speaking surgeons.

A Text-Book of Protozoölogy. By Gary N. Calkins, Ph.D., Professor of Protozoölogy in Columbia University, New York. Octavo, 349 pages, with 125 engravings and 4 colored plates. Philadelphia and New York: Lea & Febiger, 1909.

A few years ago little was known of the unicellular animal organisms, and what interest there was in the study of them was almost entirely taxonomic, but when it was found that many of them were parasites of man and were the causes of some of the most to be feared diseases, especially in the tropics, they acquired a new importance. They began to be studied with the same zeal and by much the same methods as the bacteria, and then, as so often happens, it was found that the rewards of the investigators were greater than had been anticipated, and that the nonparasitic and nonpathogenic forms of protozoa were as well worth close study as the disease-producers: "Here in those mere specks of animated jelly, which rarely measure more than the hundredth part of an inch, we find, in their simplest forms, the manifold processes of the living organism. Digestion and assimilation; respiration, with its dual action of oxidation and renewal; excretion and secretion; vitality and fatigue; reproduction together with the unfathomed mystery of fertilization and inheritance, all find expression in these simple animals, and raise the lowest protozoön immeasurably above the most complex of nonliving substances." This quotation from the author's preface shows how the study of these humble creatures may lead to an unravelling of some of the deepest of the biologist's problems. The subject, as lucidly presented in this book, is full of interest in this sense, as well as of practical importance to the medical man in his study of disease.

In the first part of the work, the most interesting part, Calkins describes the protozoa in general, their morphology, physiological activity, and various modes of reproduction. It has been the fashion, following Wiesmann, to speak of protozoa as immortal, and this author is often quoted as saying that natural death is the penalty which higher animals must pay for the privileges of differentiation. Leaving aside the very evident objection that a being is not immortal if it loses its individuality by dividing into two or two hundred separate entities, even though the protoplasmic elements of which it was originally composed may still exist in its descendants, Calkins shows very conclusively that protoplasm itself passes through the regular stages of youth, maturity, and old age, and that the protozoa, the successive generations being regarded as an "individual," as surely decay and die as do the individual metazoa produced by the successive generations of the germ cell.

In the final chapters the various parasitic protozoa, especially those pathogenic to man, are studied in their various life cycles. Among them the author includes the Negri and the Guarnieri bodies as the true pathogenic protozoa of rabies and smallpox respectively, and not mere cell inclusions. For students of medicine there is no more authoritative and satisfactory treatise on protozoa in the English language.

Medical Inspection of Schools. By A. H. Hogarth, M.B., B.Ch., Oxon., D.P.H., County Medical Officer of Health for Buckinghamshire; Assistant Medical Officer (Education), London County Council; Medical Officer Mansion House Committee on the Dwellings of the Poor. London: Oxford University Press, 1909.

This little book is written for the examiners in the elementary schools of England, but much contained therein is equally applicable to the conditions in this country. The first few chapters are devoted to the history of school inspection work in England, to summaries of the legislation on the subject in the various civilized countries, and to a strong appeal for more thorough legislation, conscientious administration, and liberal financial support in this important line of work. The denunciation of British lethargy is somewhat scathing. General and local organization of school hygiene is discussed and the duties of the school doctor and nurse, and the best way of carrying out those duties are described. The advantages of the formation of school clinics insuring proper treatment of the children receives a strong plea, and the book ends with brief summaries of causes, symptoms, and results of the more common diseases affecting school children. An appendix contains a number of official documents relating to the subject. The book is not deep or exhaustive, but it is well written, and is a useful one to be read by any man entering for the first time upon the duties of school inspection.

Verhandlungen des Vereins Deutschen Laryngologen, 1909. Herausgegeben von Dr. med. Felix Blumenfeld, Wiesbaden. Würzburg: Curt Kabitzsch, 1909.

The papers in this book have already appeared in current special journals and call for no comment here. They number twenty-three in all, some of them being fully illustrated. It is a worthy publication of the society whose scientific transactions it records. A few errors as to the page on which a given article appears have unfortunately crept into the table of contents.

Neurasthenia. By Gilbert Ballet, Professeur agrégé à la Faculté de Médecine de Paris, Médecin de l'Hôtel Dieu, Président de la Société de Neurologie. Translated from the Third French Edition by P. Campbell Smith, M.D. Illustrated with seven figures. New York: Paul B. Hoeber, 1909.

The first two editions of this book were produced by Prof. Ballet with the cooperation of Prof. Proust. The present edition has been undertaken since the latter's death. It shows no fundamental alterations of the original work, but additions have been made to the chapter on differential diagnosis and to the chapters on psychotherapy and diet. Further attention is paid also to new developments in the treatment of intestinal disorders so frequently found in neurasthenic states. The original title of the book is "L'Hygiène du Neurasthénique," and it formed one of a series of works on hygiene. It is devoted chiefly "to the laying down of the hygienic measures requisite for the prophylaxis and treatment of neurasthenia"; but it gives also a fairly good general description of the affection, both in its commoner and rarer forms, as it concerns the adult. The mental side of the picture is more completely described, perhaps, by others. Under treatment the routine use of drugs is condemned. Special establishments are recommended where the open-air treatment can be carried out. Appealing to the patient's "higher mental levels," as advocated by Dubois and others is "futile," the writer thinks, until after the patient's general condition has considerably improved. The book appears to have a practical trend throughout and the meaning, even in the translation, is usually clear. Diet, psychotherapy, hydrotherapy, exercise and gymnastics, and the effect of climate, are all considered in their application to treatment of the various types of the disease.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-fifth Annual Meeting, Held in St. Louis, October 12, 13 and 14, 1909.

THE PRESIDENT, DR. JOHN A. WITHERSPOON, OF NASHVILLE, TENN., IN THE CHAIR.

(Concluded from page 752.)

President's Address: "Medical Education, Past, Present, and Future."—Dr. JOHN A. WITHERSPOON of Nashville, Tennessee, selected this topic and, among other things, said that being the largest independent medical society in this country, it should go on record as standing for more than social and scientific work in its meetings; it should stand firmly for medical education in its highest sense of progress and wield its influence to bring about reform in medical teaching by insisting (1) on every State within its territory having uniform medical laws; (2) that none but men of culture and strictest integrity be placed on examining boards, and that politics be kept out of all medical transactions; (3) that colleges not having equipments to teach modern medicine should be condemned, and that no one should assume the responsibilities of teacher who is not by training and natural talent especially fitted to impart and instruct others; (4) that no college should be recognized that did not insist upon sufficient preliminary education and mind training of every student to receive and digest modern medicine as an entrance requirement, and a standard curriculum, in which full laboratory and clinical facilities will insure that none but good and well qualified men will be graduates; (5) that all schools should give prominence to the teaching of hygiene and sanitation, departments sadly neglected in the past, but in preventive medicine so necessary for the protection of our people from infectious diseases, either endemic or epidemic; (6) we should insist upon the fact that colleges must have endowment, and that no philanthropy was more needed or deserved, and none would give greater returns both by insuring the people that none but competent men would belong to our profession and financially because they would enforce laws which would forever bar the entrance of epidemic scourges into the ports of this, the grandest and most glorious country that was created for the enjoyment of mankind.

Modern Surgery of the Digestive Tract.—Dr. JOHN B. DEAVER of Philadelphia stated that the two prevalent conditions of the stomach which might be considered grave menaces to the life and health of the patient were carcinoma and ulcer. It was out of the question that carcinoma anywhere could be considered as offering any opportunity for the display of medical agents, and we had gradually come to a realization that the same held good of gastric ulcer. Our problems as regarded these grave and not infrequent conditions were manifold. They might be summed up into several subdivisions, diagnosis, propriety and method of surgical intervention, and the results of surgery of the stomach. It was a lamentable fact that diagnostic methods and results in disease of the stomach had lagged far behind the improvements in surgical technique and pathological experimentation. It was customary among those who decried modern surgical tendencies to refer to the inferior diagnostic acumen of surgeons, yet here we had an instance in which the diagnosis of important and vital conditions had been entirely mistaken until the surgeon had shown the way. It was to the surgeon that credit must be given for showing that carcinoma of the stomach was generally recognized long before it had reached this final stage. The exploratory operation, so called by its opponents, but more rightly considered an early operation on early symptoms, was responsible for this. Observation of the living pathology in these cases had shown us that carcinoma of the stomach often made its presence known early in its course by signs, which to the experienced observer, were definite and often unmistakable. In any person at, or beyond middle age, the subject of a persistent, grave dyspepsia, with progressive loss of weight and strength, should be looked upon with suspicion. Anorexia, and, according to Kocher, especially that form of it which manifested itself in an aversion to meat, should be enough to cause a careful study of the case. Often a slight epigastric tenderness and a feeling of oppression after eating even the lightest of foods, would be the first symptoms to come to the patient's attention. Early operation must be considered as justified when we thought of the certainly fatal outcome of every unoperated case of gastric carcinoma, and of an overwhelming majority of those operated even before the disease had reached its final stages. In cancer of the stomach excision, where this was possible, and gastroenterostomy, where we could only hope to suitably drain the stomach, offered us the only hope of permanent cure or of temporary relief. Our technique was good, the mortality of pylorectomy was low, that of gastroenterostomy almost nothing. Our main difficulty, and one which seemed most hard to overcome, was to bring the cases to operation early enough. He would not say "operate for dyspepsia," but he would advise operation in permanent, grave dyspepsia in those of middle age; even when there was no apparent anatomical cause. Operation but too often showed the root of the evil, even then so extensive as to defy efforts to remove it. Gastroenterostomy as a cure for gastric ulcer now occupied an undisputed place. It must not always be recommended; for instance, in acutely bleeding ulcers it was worse than useless. Its initial mortality in benign conditions of the stomach was less than three per cent., in the hands of experienced operators, and its complications almost none. The end results were good, and observers such as Mayo Robson, Czerny, and others reported definitely from 75 to 90 per cent. of cures. It would be seen from the foregoing remarks that progress in surgery of the digestive tract had been great, but that much yet remained to be done. It was also evident that we must seek advances not principally in the elaboration of minor technical details or operative procedures, but by endeavoring to utilize thoroughly the recent great advances in the normal and pathological physiology of the digestive tract.

The Pectinate Line—Zone of Rectal Pathology.—Dr. J. RAWSON PENNINGTON of Chicago said that embryology furnished an explanation of the frequency with which disease attacked the junction of the anal canal and the rectal ampulla. The region in question was one of the points of coalescence of the two primitive germ layers, ecto- and entoderm. This junction of the anal canal and rectal ampulla was marked by the pectinate line and gave rise to the crypts and columns of Morgagni. The histological structures entering into the formation of this coalescence being different, we would expect the diseases affecting the area to be different also, and that was what we found.

Medical Treatment of Exophthalmic Goiter.—Dr. S. P. BEEBE of New York detailed the results of serum treatment of this disease and said in many respects it was very encouraging. He had seen the effects of surgery as practised by a variety of surgeons upon these cases. Men of very limited experience should not operate in cases of exophthalmic goiter. None but the most experienced surgeons should undertake this operation. The operation required not only great judgment and skill in its execution, but in the preparation of the patient. No greater harm could be done than when a number of young surgeons took it for granted that this was the operation to do and they did it right away. They should serve a long appren-

ticeship under surgeons before doing such a formidable operation

Postoperative Results in Exophthalmic Goiter and Tumors.—Dr. George W. Crile of Cleveland, O., presented a report based upon a total of 278 operations upon the thyroid gland. He had operated upon fifteen malignant tumors. In thirteen the diagnosis was either made or suspected. All of these died either as operative deaths or as recurrences. In two, one a sarcoma and one a carcinoma, malignancy was found in the routine pathological examination and was not suspected clinically. His personal experience and the reports from a number of clinics led him to conclude that cancer of the thyroid was at present rarely, if ever, diagnosed in its curable stage, and the occasional cure was accidental. Among the benign tumors and plain goiters there was one fatality. In malignant tumors diagnosed clinically the postoperative results were as uniformly unsuccessful as they were successful in plain goiters and benign tumors. A study of his series of seventy-two operations for Graves' disease, presenting as they did numerous and complex symptoms, and involving many organs as well as the most fundamental vital processes, impressed him with the great, almost unsurmountable difficulty, or even the impossibility, of compiling any statistical table that accurately represented the net clinical results. The longer the disease had existed, the greater the organic changes, and in consequence the more tardy the convalescence, and if the organic lesions had progressed to a certain degree the operative risk was greatly increased and the risk might become an operative impossibility. In these desperate cases, when operative recovery took place, the convalescence would be correspondingly slow, and stormy and incomplete. The ship had gone upon the rocks and it was the wreckage that we were dealing with. Now, he had seen no case that was not benefited by operation. The majority regarded themselves as cured. Acknowledging all the difficulties and shortcomings, he knew of few cases that experienced such deep and fundamental relief as cases of acute toxic Graves' disease operated on successfully before organic changes of importance had occurred.

Primary Bilateral Ligation of the Upper Poles of the Thyroid Gland for Exophthalmic Goiter.—Dr. J. H. Jacobson of Toledo, Ohio, said that in all there had been eight cases of pole ligation; one, in which a single upper pole was ligated, resulting in a cure; one, in which the upper and lower poles on the same side were ligated, which was followed by improvement; and six in which both upper poles were ligated; in one of these there was no effect. The patient was moribund at the time of operation, and of the remaining five, four were symptomatically cured, and one had been very markedly improved. This case was too recent to give the final result. All of the patients expressed themselves as being greatly pleased with the operation and its effect. He presented the following conclusions: 1. Ligation of both poles of the thyroid gland, acted, first, by diminishing the blood supply to the gland and thus diminishing immediately its activity; second, by directly diminishing and preventing the gland secretion from entering the general circulation by way of the main lymphatic channels which left the thyroid body at its upper poles; and, third, by causing a subsequent atrophy of the gland itself. 2. The operation of "pole ligation" was much easier to perform than ligation of the thyroid vessels, and might be as effective as a partial thyroidectomy. 3. It did not disturb the blood supply of the parathyroid glands, nor endangered the recurrent laryngeal nerve. 4. Theoretically, at least, and from the simplicity of its performance, it would seem that "pole ligation" should entirely supplant the operation of simple ligation of the thyroid vessels in Basedow's disease, and in many cases the necessity of partial thyroidectomy. 5. As a preliminary operation to partial thyroidectomy for Basedow's disease, it would be found of great value. 6. At the present time we were warranted in saying that "pole ligation" offered the prospect of cure in many cases and of lasting improvement in others. 7. The operation of "pole ligation" was a safe one and in skilled hands had no mortality.

The Value of Thyroidectomy in the Treatment of Catatonic Dementia Precox.—Drs. Allen B. Kanavel and Louis J. Pollock of Chicago summarized the results obtained in operations upon twelve cases of this disease, operated upon at the Dunning Institution for the Insane. The cases were studied by Dr. Pollock and submitted to operation. Dr. Kanavel reported his results as follows: There was absolutely no result in any of the old cases. Of three cases operated upon in the so-called favorable stage, two showed marked improvement, lasting in one case for two months, and in the other case for six months. The third case showed no change at all. The two cases which showed temporary improvement relapsed at the end of the periods mentioned and were now in practically the same condition they were before the operation. The pathological examination of the glands did not show changes favoring the diagnosis of thyreotoxicosis, although the changes were compatible with it. Berkley still reported favorable results in his cases, but the results of the investigation in the present series could not but lead one to a most conservative report concerning the value to be derived from the procedure.

Surgical Treatment of Exophthalmic Goiter.—Dr. A. J. Ochsner of Chicago said that exophthalmic goiter became a surgical disease after it had been shown that internal treatment and treatment by serum were of no avail. When cases had advanced to the point of great interference with the function of the heart muscles and of the nervous system, then the results from surgical treatment were not promising.

Dr. Herman Tuholske of St. Louis said that the thyroid gland was an organ necessary to life. Without it trophic changes would be inaugurated of such a character as to result in the decay or death of the patient. This one factor should be kept constantly in mind in considering the various phases of this subject. Again, it was the experience of all surgeons that there were a number of patients with exophthalmic goiter who would get well with or without treatment, and while that number was small, still it became a factor in discussing the value of the remedies that had been used in the cure of this disease.

Dr. Arthur R. Elliott of Chicago said the tone of the papers read was preponderatingly surgical. This was in keeping with the present tendency which had initiated a movement strongly towards the assumption that Graves' disease was a surgical affection, but perhaps not always in the interest of rational therapy. This was probably to an extent due to the fact that medical measures were unsatisfactory and unsuccessful in a certain proportion of inveterate cases of Graves' disease. It was not to be forgotten, however, that the medical practitioner came in contact quite frequently with many cases of thyroidism in various stages and degrees of intensity, many instances of which underwent a symptomatic cure, if we could speak of such a thing as curing this disease, and a large proportion of them improved under measures intelligently applied, such as rest, tonic treatment, dietetic therapy, etc. This was true not only of the milder and the chronic types of thyroidism, but of many instances of more acute Graves disease, as those who practised before the days of thyroid surgery could testify. Without directing any criticism against the surgical treatment, which in the hands of expert and experienced surgeons had amply justified itself by results, it was a fact that in the hands of the average surgeon the operation of partial thyroidectomy was attended by a high mortality.

Dr. J. Henry Carstens of Detroit said the symptoms of

this disease were very obscure, but there was one symptom he wanted to emphasize. Take a young woman who had repeated attacks of palpitation of the heart, without any particular cause, without any other symptoms such as protrusion of the eyes, enlarged thyroid, etc., we should bear in mind constantly Graves' disease.

Sigmoid Diverticulitis.—Dr. Daniel N. Eisendrath of Chicago stated that there had been many cases of autopsy reports of peritonitis due to perforation of these diverticula, but their rôle in the production of definite clinical pictures was not known until the paper of Gräser in 1898. Diverticula of the sigmoid were as a rule acquired. They might occur anywhere in the large intestine, but were most common in the sigmoid, ending abruptly at the rectum. Unless they underwent secondary changes they did not give rise to any symptoms. Telling in 1908 collected 105 cases. Of these nearly one-half showed no clinical symptoms, but were found by accident at autopsy. Diverticula were most apt to occur in two rows at either side of the gut. They might, however, develop at the mesenteric attachment and occur between the layers of the mesentery. In some cases they were simply protrusions of the mucous membrane into the appendices epiploicæ, while in others they formed definite pouches, either oval or flask shape. One of the most important factors in the production of diverticula was muscular weakness incident to old age and the presence of considerable fat in the intestinal wall which favored a pushing out of the mucosa. The most frequent secondary pathological changes were (a) infection of the general peritoneal cavity without perforation; (b) acute or gangrenous inflammation resembling the same pathological form of appendicitis: (c) acute perforation, formation of an abscess, or general peritonitis. Attention was called to the fact that the preceding pathological forms greatly resembled corresponding types of appendicitis. The other varieties not occurring in appendicitis were the form of fistulæ between the diverticula and the bladder or the bowel and the development of a hyperplastic inflammation greatly resembling in appearance carcinoma. The latter form caused great thickening of the gut wall, so that its lumen was reduced to a minimum. The clinical cases could be divided into the acute and chronic forms. To the former belonged the catarrhal gangrenes, with or without localized abscess formation, and perforative with general peritonitis. To the chronic belonged the chronic hyperplastic or stenosing form; the enterovesical fistulous forms and the chronic adhesive form caused acute or chronic intestinal obstruction. The acute forms resembled the corresponding forms of appendicitis, except pain and tenderness, rigidity and tumor formation, when present, occurring in the left iliac region. The treatment of these did not differ much from the corresponding forms of acute appendicitis and, unless the case was recognized, recurrence was apt to take place. He reported one case in which diverticula were found filled with enteroliths during the operation for hernia and a second case of general peritonitis due to perforation of diverticula. He also called attention to the fact that no doubt many of the cases of the stenosing form or peridiverticulitis had been erroneously diagnosed as carcinoma of the sigmoid.

Dr. Ernst Jonas of St. Louis said a point of practical importance was that a condition of this kind was often mistaken for carcinoma of the sigmoid, and some cases of sigmoid diverticulitis had been operated on for carcinoma of the sigmoid. Dr. William J. Mayo had reported several cases in which he removed part of the sigmoid for a condition of this kind, believing at the time of the operation that he had to deal with carcinoma, and only after careful pathological examination of the specimen did he believe that it was a chronic inflammatory condition due to diverticulitis. The weakness of the muscular walls, which was mentioned as an etiological factor, must either be hereditary or acquired. Very little could be done for the patient where the weakness of the muscular walls of the sigmoid was hereditary, but in the acquired condition we had first hypertrophy and later on dilatation and weakness of the muscular wall resulting whenever there was any obstruction further down. Adhesions around the sigmoid, which pulled the sigmoid out of place and interfered with the drainage were the cause of deverticulitis. Another cause for diverticulitis was a slight chronic ulceration in the particular place where diverticula were found.

Dr. J. Rilus Eastman of Indianapolis was reminded of two cases in which the abdomen was opened for what was obviously an acute generalized suppurative peritonitis, which was ascribed to the rupture of an inflamed appendix. Every one present had opened the abdomen for these indications when there was no evidence whatever pointing to any infection arising in the upper abdomen, but every bit of evidence pointed to an infection arising from the lower zone of the abdomen. We had cut down upon the appendix and found suppurative peritonitis with the escape of a thin fluid filled with flocculi, followed by a thick, creamy pus. We had examined the appendix and found it practically normal. We had removed the appendix not knowing what else to do with it, and we had either irrigated or left the abdomen dry and put in a large tubular drain. In a case which he had seen, within a month, of this general character, he found that the adhesions in the intestines were upon the left side, and while it would be absurd for him to say in the presence of such meager evidence that he had to deal with a condition like that described by Dr. Eisendrath, still in the future he should be very cautious and be on the lookout for infections arising from these diverticula in the sigmoid, because he was reasonably sure that a sigmoid diverticulitis, followed by a rupture, had given rise to more cases of general suppurative peritonitis than we had imagined, and if we were to consider adhesions in the future we would not only look to the right side of the abdomen for the cause of this suppuration, but also to the left side occasionally.

Dr. Edwin Walker of Evansville operated last week on such a case as Dr. Eisendrath had described. There was an abscess on the left side exactly like an appendical abscess. He was reminded of the case of a man which was diagnosed as carcinoma of the sigmond flexure, and the post-mortem findings were precisely like those described by him. It was thought at the time the trouble was inflammatory, but he thought there was perforation and inflammatory trouble. This case occurred twelve years ago, and in the light of what had been said to-day it was without doubt a case of sigmoid diverticulitis.

Dr. Channing W. Barrett of Chicago said there were points of practical interest in this paper. First, the point Dr. Jonas brought out of an acquired or congenital weakness of the bowel walls. It was likely in many cases that constipation caused the dilatation and that resulted in overdistention of the abdomen, causing separation of the muscle fibers and this furnished opportunity for the mucous membrane to herniate between the weakened muscle fibers. In an acquired condition of this kind, we should do away with any cause for overdistention; but instead of being able to do nothing in the congenital condition, it was all the more important that these conditions be looked after. Another practical point was we had been inclined to deal with enlarged and inflamed appendices epiploicæ as though it was merely a question of having to control hemorrhage. We might not only have to deal with hemorrhage, but with the communication of the bowel, the same as in dealing with the appendix. Just the other day in dealing with a pus tube he felt it was desirable to cut off several of these appendices epiploiccæ and deal with them as he would with a hemorrhage.

Dr. Robert F. Wilson of St. Louis differed from Dr.

Eisendrath and others in reference to acquired diverticulitis. He still clung to the old theory, namely, that all cases of diverticula of the sigmoid were congenital and we must go back to the embryological formation in the primitive hindgut from where the sigmoid was developed and look there. He did not believe the conditions mentioned caused diverticula of the sigmoid, but it was a weakened condition in the gut that was the sole cause.

Dr. R. H. Barnes of St. Louis believed diverticula of the sigmoid, as well as of other parts of the bowel, were more common than most physicians or surgeons thought. These diverticula did not always cause trouble and might only be recognized postmortem. The majority of cases of diverticula were congenital. There was a localized weakness of the muscular wall of the bowel which formed them and these became infected through the fecal matter or from some other cause and then we might have the symptoms of diverticulitis. The majority of cases were not recognized from the clinical symptoms and for that reason were overlooked.

Gunshot Wounds of the Thigh; Amputation at the Hip Joint.—Dr. William Britt Burns of Memphis reported twenty cases of gunshot wounds of the thigh. He had observed a number of others. He had been impressed with the destructiveness of tissue and with his inability to get good results on account of lack of repair on the part of the tissues and the seeming susceptibility to infection. Every one of the cases was thoroughly and freely opened on all sides and all kinds of material removed from the wound by scraping, by the use of scissors, removal of spiculæ of bone, establishing proper drainage, dressing the thigh and using every effort to prevent sepsis, and yet the results had not been what might have been expected.

Dr. H. O. Walker of Detroit had seen a few cases of gunshot wounds of the thigh that were not only made with bullets, but with buckshot and with small shot. He had opened the wounds in these cases freely, removed thoroughly all particles of clothing and other material from the wounds and the patients had all recovered. He had not had to resort to amputation in any one of the five cases which he now recalled.

The Advantage of Pfannenstiel's Incision.—Dr. H. O. Walker of Detroit said the fibers of most of the abdominal muscles ran either diagonally or transversely, an exception to this was the recti. The principal blood vessels supplying the abdominal region were the two superior and inferior epigastrics and their branches. These all ran in a general way parallel to the recti muscles. It was never necessary to cut but the two inferior epigastrics and this was not always required. The nerves supplying the abdominal region ran in a general way parallel to the muscle fibers also. The prevention of hernia could no doubt be aided by incisions in line with the muscle fibers. It was more necessary to respect nerve fibers in incisions than blood vessels, generally speaking. The cosmetic advantages of cross cuts were very apparent. Pfannenstiel's cross incision fulfilled all of the above requirements. Thirty-eight cases had been operated on by this incision through which practically all possible pelvic operations had been carried out.

Dr. George Gellhorn of St. Louis said the advantages of the Pfannenstiel incision were becoming more and more appreciated in America. It had many advantages over the longitudinal incision. He had used this incision for a number of years and had not yet seen a case of hernia, although in four cases he had disturbances of wound healing. There was, however, a limit to the use of this transverse incision, in that the larger tumors, which extended about half way to the umbilicus, were not as easily removed through this incision as they were through the longitudinal incision, but outside of that fact the advantages were all in favor of this transverse incision.

Dr. Walker, in closing the discussion, said that we could remove very large tumors through this Pfannenstiel incision and could go still further with it, in that we could reach the stomach, pancreas, and gall-bladder, and do any surgical work which might be required to be done on any of these organs. It was an incision that had a great many advantages over the longitudinal incision in many operations in the pelvis.

Sarcoma of the Prostate.—Dr. Joseph Rilus Eastman of Indianapolis said it was certain that of malignant neoplasms of the prostrate, carcinoma was much the most common, although as Barth stated years ago sarcoma of the prostrate was doubtless less rare than had been imagined and owing to the circumstance that until recently very little, if any, distinction was made between carcinoma and sarcoma, there had been, perhaps, some misconception on this point. That malignant disease of the prostate was much more common than had been appreciated heretofore, might be inferred from the experience of such careful observers as Hugh Young, who in 500 cases of prostatic enlargement found 100 cases of carcinoma, or one case of carcinoma to every four of prostatic hypertrophy, and although there had been reported less than thirty cases of sarcoma of the prostate of primary origin in the gland, which had been satisfactorily proven to have really been sarcomata, no doubt in view of the general indifference as to microscopical examination many cases of sarcoma of the prostate had been carelessly called carcinoma or even tuberculosis. The case which the writer reported was one of spindle celled sarcoma of the prostate occurring in a man, 27 years of age, and apparently running a course covering five years and having many characteristics in common with tuberculosis. Upon microscopical examination the masses of tissue at the base of the villi removed by the curette were found to be infiltrated and degenerated, showing a preponderance of embryonic connective tissue cells with a relatively small amount of mucoid intercellular substance. The tissue removed from within the capsule of the prostate was made up of the same spindle shaped connective tissue cellular elements.

Stricture of the Male Urethra.—Dr. E. O. Smith of Cincinnati said that stricture of the urethra was an abnormal narrowing of some part of that channel which interfered with the free outflow of urine, due to either muscular spasm or to organic changes in the walls of the urethra. Abnormal narrowing of the external meatus should be divided very carefully. If cut too widely the patient would be left without projectile force. Spasmodic contraction of the urethra was usually due to acid urine, sexual excesses, fissure of anus, hemorrhoids, pin worms, cantharides, turpentine, etc. Strictures following traumatisms were much more stubborn to yield to treatment and the band of scar tissue might have to be dissected out through an external incision. The popular idea that a rapid cure of gonorrhea caused stricture was not based on facts, but on the contrary the longer the duration of the gonorrheal inflammation the more liable was the patient to have a stricture. In fact, it was the exception for an urethra to become absolutely normal after one prolonged attack of specific urethritis. The urethra behind the constricting band became dilated, a pouch was formed which was a most excellent container and incubator for the germs of sepsis, which might lead to periurethral abscess and possibly to urethral fistula. All this argued for an early treatment of stricture. Stricture was suspected when there was gleet, frequent micturition with a tardy beginning of the stream, dribbling after urination, with possibly some hypogastric pain. In examining for stricture great care and gentleness must be practised, otherwise a false passage might be produced. Treatment was both general and local, diet, bland and not stimulating. Alcohol and tobacco were to be excluded. Sexual excesses were to be avoided. There should

be no exposure to cold and wet. Local treatment was that of gradual dilatation. Begin with the largest sound or bougie that could be easily passed. This might be only a filiform. Gradually increase the size of the sounds used. Treatments to be every four or five days in the beginning, all the time being surgically clean with one's hands and instruments. Urethral chill and shock could usually be prevented by giving the patient ten grains of quinine and five drops of tincture of aconite about twenty minutes before the treatment. Epididymitis might, but seldom did, follow the passage of a sound. Strictures that did not yield to the gradual dilatation treatment were the exception. Internal urethrotomy should not be attempted except by those skilled in genitourinary surgery as there was a possibility of doing great damage. External urethrotomy was seldom necessary in the treatment of stricture, other than those due to traumatism.

Burns.—Dr. A. H. Barkley of Lexington said burns were the most frequent injury in civil life and caused the most agonizing suffering and condemned the patient to a life long mutilation of the most repulsive character. The severity of a burn depended on the character and degree of the heat, the length of time it was applied and the thickness of the cutaneous surface. The author reported a case of a male, aged 56, an engineer, who was burned by hot water and steam. Patient was 5 feet 10 inches and weighed 160 pounds at the time he was injured. He has 19 square feet of skin on his body. Of this 10 square feet were burned off, of which four square feet were of the third degree. Recovery was complete. The interesting points in this case were the area of skin burned, no contractures, no complications, and healing without skin grafting.

The Treatment of Some Forms of Neuralgia by Deep Injections.—Dr. D'Orsay Hecht of Chicago said that his first case was injected November 20, 1906, and his last September 30, 1909. During the period between these dates he had injected forty-eight cases of tic douloureux. Eight cases besides this number were rejected because they were unsuited for this treatment. In all cases the diagnosis was made on the strength of the short, sharp paroxysms of pain so characteristic of the condition, and after careful inquiry into all conditions of the teeth, jaws, mouth, nose, and accessory nasal sinuses, which sources were frequently responsible for pain which might quite closely simulate the disease. One must be mindful of the fact that tumors involving the fifth nerve, as well as syphilis and migraine, could give rise to pains that might readily deceive as trifacial neuralgia. In many of the cases external skiagraphs were taken, and where these were felt to be unsatisfactory or unreliable, intrabuccal film skiagraphs were supplemented for the purpose of eliciting better detail, thereby affording a better means of localizing possible dental or oral sources of irritation. Among the rejected cases were those in which pain was caused by the presence of abnormal dental conditions, post-influenzal nasopharyngeal infections, sinus disease, and hysteroid conditions. In point of therapeutic results, thirty-two cases were distinctly benefited; eight were improved; five were unimproved; and three were aggravated. Of the thirty-two benefited, one patient was free for one year and eight months. The shortest free interval had been two weeks. Recurrences had varied, in the successful cases on an average of one year. A given number had returned for reinjection upon the first reappearance of pain in four months, some six, some ten, some one year, some sixteen and eighteen months. The variability was accounted for by the personal equation and the accuracy with which the alcohol was deposited in, at or near the nerve. In the entire series the patients required from one to five injections, this number sufficing for a permanent cure in the non-symptomatic neuralgia. An 8 per cent. salt solution of body heat injected in the amount of from 90 to 120 centimeters seemed to act to better advantage than lesser amounts of different temperature.

What Women Should Know in Regard to Uterine Cancer.—Dr. J. Henry Carstens of Detroit suggested that the medical profession agitate this subject in the lay press and on every occasion talk cancer. The doctor should talk about it in order to arouse the public as to its importance, because it was a great menace. He had suggested to the Michigan State Board of Health that they get up a circular which should be in the hands of every woman in the cancer period of life. This circular should be in the possession of county societies and of every physician and should be given to every woman in the cancer age. The menopause came on gradually, rarely suddenly. It was not preceded by excessive flowing, or discharge, or pain in a healthy woman. By the cancer period was understood those years after forty, although rarely it might occur earlier. The first symptoms of cancer were: 1. Profuse flowing, even if only a day more than usual. Flowing or spotting during intervals or after the use of a syringe or the movement of the bowels. 2. Leucorrhea, if not existing previously. If not existing, but getting more profuse, watery, irritating, or producing itching, it was a very suspicious symptom. 3. Loss of weight if no other cause was apparent. Pain in the region of the womb, back, or side. If any of the above symptoms occurred after the age of forty or forty-five, a woman should seek prompt relief and insist on a thorough investigation of the cause and prompt treatment. Cancer was always at first a local disease and could be removed if early recognized, and an absolute permanent cure brought about.

Problem of the Insane and the Defective.—Dr. Leo M. Crafts of Minneapolis read a paper on this subject, which embodied a consideration of past methods of care or neglect of these conditions by society, the present lines of care and nurturing of them, enabling their more frequent and prolonged survival and activity, including procreation. It also took up the conditions in the present social state tending to greater strain on the nervous system, with the increasing lines of neuropathic heredity thus engendered. It dealt with the various state and national statistics bearing on the questions and pointed out the present absolute lack of regulation or control of the free activity of these classes in producing a posterity, and the author offered suggestions for advisable legislation for effective control of such subjects.

Genital Canal Block Following Neisser Coccus Infection.—Dr. Chas. Barnett of Fort Wayne exhibited a number of photographs illustrating the pathology found in genital canal block. He contended that sterility was not the greatest factor, but that the pathology causing the block and following it, especially the retention of cysts, were "nagging" the man's body continuously. He believed that prostatectomy, unwittingly, frequently opened up the vesicular field of drainage. He considered that in the correction of this pathology the surgical question was a difficult one when the final results anticipated normal function. It was true that in some cases the cysts were emptied and the block removed. This relieved the symptoms temporarily, but the time might finally come when a recurrence would happen indicating that a thorough removal of the field that was pathologic was necessary in order to prevent a further extension of the diseased process, rather than to try to save a crippled canal surrounded by contaminated glands that would never assume complete resolution.

Some Reflex Neuroses Arising from Nasal Abnormalities.—Dr. J. A. Stucky of Lexington, Ky., emphasized six salient points as given by Ziegler to be borne in mind when searching for reflex neuroses and added a seventh. 1. Eye and nose must first of all be thoroughly

examined and excluded or accepted as exciting cause. 2. A careful differentiation of those reflexes manifested in common by the eye and nose. 3. Eye strain from whatever cause, whether ametropia, subnormal accommodation, or intranasal pressure, should be corrected to exclude the eye as a factor. 4. Pressure contact in the nose in every instance must be relieved, as the symptoms of such pressure of hyperesthetic areas were so like the eye in their reflex manifestations. 5. Every obstruction to free breathing in the superior part of the nose should be removed. 6. Recurrence of any reflex neurosis demanded reexamination, renewed search for and correction of original exciting cause. 7. Lithemic conditions, faulty intestinal metabolism of whatever type, must be corrected and deserved careful consideration in every reflex neurosis whatever be the exciting cause.

Acute Dilatation of the Stomach.—Dr. Edwin Walker of Evansville, Ind., said the treatment of acute dilatation of the stomach consisted of prompt evacuation of the stomach by the stomach tube, followed by copious lavage. It would be an excellent practice in all post-operative cases whenever vomiting was prominent to resort to this measure. In order to release the pressure on the duodenum the patient should lie on the abdomen, with the foot of the bed elevated, or in extreme cases a knee-chest position. It was astonishing in grave cases to see the prompt relief given by these measures. The lavage should be repeated when the fluid reaccumulated or if the condition of the patient did not improve. Strychnine and physostigmin had been given. Rectal feeding should be given.

Muscle Rigidity; An Important Physical Sign of Disease Within the Chest.—Dr. F. M. Pottenger of Monrovia, California, described this sign.

Prophylaxis of Pellagra.—Dr. C. H. Lavinder of Washington, D. C., in a paper on this subject reviewed very briefly the theories as to etiology and discussed two points: First, the communicability of the disease, and, second, the practical application of its alleged relation to the use of spoiled corn as a food stuff. He thought that our experience in the United States was too limited for us to base conclusions thereon and that it would be unwise to reject the accumulated observations and deductions of other able men in other countries whose experience had been so much wider and fuller than our own. Since practically all observers agreed that the disease was not communicable, and since quarantine measures were not in force against it, he thought it was not necessary in the present state of our knowledge to adopt quarantine measures against the disease. So far as its relation to spoiled corn was concerned, he admitted that much of the evidence was unsatisfactory, but since practically all theories of the disease took corn into more or less essential consideration and since Italy, in her determined fight against pellagra, had based most of her procedures on this theory and was claiming a fair share of success, we could not at present do otherwise in our prophylactic measures than recognize some relationship between corn and pellagra.

The following papers were also read: "The Problem of a Federal Department of Health," by Dr. Liston H. Montgomery of Chicago; "Therapeutic Renascense," by Dr. R. A. Bate of Louisville, Ky.; "Some Comparisons of the Physiological Action of Preparations of the Heart Tonics of the Digitalis Series," by Drs. E. Mark Houghton and H. S. Yntema of Detroit, Mich.; "Atony and Tonics," by Dr. Nathan Rosewater of Cleveland, Ohio; "The Abuse of the Obstetrical Forceps," by Dr. J. O. Jenkins of Newport, Ky.; "Some Pediatric Cases Found in General Practice," by Dr. Geo. Allen Staples of Dubuque, Ia.; "Infant Feeding in Country Practice," by Dr. Charles W. Carter of Clinton, Ill.; "Pellagra," by Dr. C. H. Lavinder of Washington, D. C.; "Clinical Types of Pellagra, with Exhibition of a Case," by Dr. C. M. Rudolph of Birmingham, Ala.; "Pellagra Symptoms and Report of Cases, with Exhibition of Patient," by Dr. Geo. A. Zeller of Peoria, Ill.; "The Socialistic Future of Medicine," by Dr. Maynard A. Austin of Anderson, Ind.; "Alcohol," by Dr. John H. Landis of Cincinnati, Ohio; "Camp Sanitation," by Dr. S. C. Stanton of Chicago, Ill.; "Improved Technique for Dissection of Vulvovaginal and Other Cysts, and Hernial Sacs," by Dr. A. J. Schoenberg of Chicago, Ill.; "Local Versus General Anesthesia," by Dr. B. M. Ricketts of Cincinnati, Ohio.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Frank P. Norbury of Kankakee, Ill.; *First Vice-President,* Dr. George W. Cale of St. Louis, Missouri; *Second Vice-President,* Dr. Wm. B. Laws of Hot Springs, Arkansas; *Secretary,* Dr. Henry E. Tuley of Louisville, Kentucky, reelected; *Treasurer,* Dr. Samuel C. Stanton of Chicago, Illinois, reelected.

Detroit, Michigan, was selected as the place for holding the next annual meeting.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF PEDIATRICS.

Stated Meeting, Held October 14, 1909.

Dr. Eli Long in the Chair.

A Case of Pyloric Stenosis Cured Without Operation.—Dr. Linnæus La Fétra presented a male infant, nine months old, the only child of Jewish parents. The child was born at full term. He was breast fed until his admission to the Babies' Hospital on June 15. The baby vomited from fifteen to twenty times a day, usually just after, but always between, feedings. This vomiting was projectile in character. He was always constipated. There was a constant loss of weight from birth. The peristaltic wave was noted at first because of the tense abdomen and some abdominal tenderness. The child was at first thought to be suffering from pylorospasm. Four days after admission the peristaltic waves were first seen and felt, and they became very marked up to June 30. The waves could be seen across the room, and the thickened wall of the stomach could be picked up between the fingers. The "spool" of thickened pylorus was easily made out. Only once had Dr. La Fétra seen any such peristaltic waves in a case other than pylorus stenosis with marked vomiting. This child was a Mongol, one year old. The mother had noticed a peculiar swelling on the abdomen when the child was given a bath. There was no more vomiting than occurred in normal babies. In this child the wave was marked, the stomach was thick, and the artery on the greater curvature could be felt pulsating. The child presented by Dr. La Fétra was admitted to the hospital when five months old, on June 15. His weight was seven pounds and fourteen ounces. The stomach was washed out and modified food given. On the day following he vomited two or three times. Sodium bromide, two and a half grains, was given at each feeding. On the 30th one minim of paregoric was added. From the seventh of July the baby was breast fed and the same medicines continued. The child had projectile vomiting only every second or third day. On August 4, two ounces of junket was given three times a day. There was practically no vomiting, but the infant lost weight. On August 7 the amount of paregoric was increased to three minims, and about one drachm of milk of magnesia was given each night. All this time, notwithstanding the breast milk, there was a loss in weight which on August 12 was down to seven pounds and two ounces. On August 19 the paregoric was increased to six minims, and the sodium bromide to four grains seven times a day. By September 22 there was no vomiting, and the medication was stopped. On September 27 the child developed a bronchopneumonia, having a temperature of from 101° to 103.5° F. for ten days. There was no vomiting. Since October 6 the tem-

perature had been normal, the stools were normal, and the baby only vomited occasionally. The weight had increased to ten pounds and three ounces.

Dr. La Fétra reported two other cases cured without operation. Also three cases that were operated on, all dying. In his last case, operated upon by Dr. Alfred S. Taylor, the pylorus was found very hard as well as thickened. The walls were three-eighths of an inch thick and the tissues so friable that sutures would not hold. For such cases operation was the only hope and even then the chances were slight because of the difficulties of the operation. The cases of hypertrophic pyloric stenosis differed so much that no general rule could be laid down as to medical or operative treatment. Breast milk was of the first importance and might be all that was required; sedatives, especially opium, should be used in full doses. Lavage and poultices over the stomach were of value. If scanty urine and meconium-like stools persisted and the infant lost weight steadily, operation should be considered.

Dr. Alfred S. Taylor reported the case of a child, six weeks old, who had persisted vomiting from birth. The classical symptoms of pyloric stenosis were present. One could feel the hardened pylorus and the peristaltic waves of the stomach could be seen and felt with perfect clearness. The pylorus was split longitudinally through the serous and muscular layers, thus avoiding any chance of contamination of the peritoneal cavity. The pyloric opening was readily enlarged. The child was in such a bad state of nutrition that it was though desirable to do an enterostomy into the upper jejunum, and to feed the baby through a tube. The pylorus was easily exposed; it was as hard as ivory, its muscle was very thick and friable, the sutures tearing through. Finally a diamond shaped segment of the pylorus was removed down to the mucous membrane and the wound sutured. He succeeded in getting a good sized pyloric opening. He then did an enterostomy in the jejunum and sutured in the feeding tube. On the following day, the child suddenly collapsed and died. The specimen showed the great thickness of the pyloric wall. The sutures held well. The lumen of the pylorus was sufficiently large to allow food to pass with ease.

Dr. Charles Herrman reported a case of pyloric stenosis cured without operation. He asked why symptoms of pyloric stenosis did not appear at or shortly after birth, but only after some weeks had elapsed. Westphal had tested the electrical reactions in the new born and had found that during the first few weeks of life they were very much diminished in the peripheral nerves. If the symptoms of pyloric stenosis were dependent upon increased reflex irritability, this peculiarity might explain why the symptoms were not present during the first few weeks of life.

Dr. Charles Gilmore Kerley had observed three cases of pyloric stenosis and all got well without operation. He was inclined to believe that perhaps operation was performed too early. On the other hand, if the operation was delayed too long, the resulting malnutrition made the operation all the more hazardous. It was a very difficult matter to decide just when the operation should be performed. Because of the high mortality there should be no interference until it had been demonstrated that the child's condition would be hopeless without the operation. These cases did particularly well on breast milk.

Dr. Herman Schwarz said that it was a recognized fact that these infants died shortly after the operation, apparently from giving too great quantities of food.

Dr. J. Finley Bell believed that operation should be decided upon when no fecal matter appeared; this indicated a complete stenosis, and was a positive indication for operation.

A Case of Amaurotic Family Idiocy.—Dr. Charles Gilmore Kerley presented a Hebrew child, eighteen months old, who had been under observation since he was one month old. He was never bright, never smiled, never appeared to care for, or take hold of toys, and evinced no interest in his surroundings. The child was stupid, inactive; the pulse was slow and irregular. The reflexes were absent. The pupils reacted slowly. The fontanelle was tense and bulging. A lumbar puncture was performed; the fluid was under a great deal of pressure; nothing abnormal was found in it. The child brightened somewhat, but the mental dullness and apathy continued.

Dr. Robert Grigg Reese said he had examined the eyes of the infant presented by Dr. Kerley and found lesions characteristic of amaurotic family idiocy, consisting of a white spot at the macula lutea twice the size of the optic papilla, with a brownish red, almost circular spot at its center. Hyperacousis was very marked. The ophthalmoscopic picture was due to a degenerative change in the ganglion cell layer of the retina.

Dr. George Dow Scott reported the case of a child with amaurotic family idiocy; the posterior nares was fully plugged with adenoids. The removal of the adenoids was followed by a complete recovery from the pseudo imbecility. Cases of cretinism, feeble minded children, and amaurotic family idiocy often were very difficult to differentiate and required the exercise of great care in diagnosis.

Dr. Godfrey R. Pisek said he had seen three such cases and had had a good opportunity for studying the eye grounds. One patient had a pseudoparalysis which was very marked. All the patients died before attaining the third year.

A Case of Scorbutus.—Dr. Godfred R. Pisek presented a child, thirteen months old, who had nursed for six weeks. The breast milk then became insufficient and the child was placed on a prepared food. The mother stated that six weeks previous in crawling about he had sprained his knee and was taken to a dispensary where he was treated locally by a surgeon. Upon inquiry he found that the child's mouth bled when it was cleansed and that blood had appeared in the stools on a few occasions. He also learned that the so-called "sprain" of the right knee soon passed to the left knee; then the baby was brought to the medical clinic. The baby was seen for the first time seven days ago. He had a waxy, pale color; the limbs were in a condition of pseudoparalysis. The right knee was somewhat swollen and painful. Even pressure upon the chest or ribs caused pain. The examination of the mouth showed the characteristic condition of the gums, swollen and spongy, the hemorrhagic appearance of scorbutus. The swelling of the knee had diminished considerably after a few days' treatment. There were no rickety manifestations. Syphilitic paralysis was readily ruled out.

A Case of Severe Infantile Paralysis, Showing Possibilities of Apparatus Correctly Applied.—Dr. Charlton Wallace presented this patient, showing what could be done if mechanical knowledge was applied to support paralyzed muscles.

A Case Illustrating the Proper Treatment of Weak Feet.—Dr. Charlton Wallace presented a patient who showed the typical condition of bulging at the scaphonavicular joint. She walked with her toes turned outwards and was now being taught to walk with the toes pointing straight ahead. Exercises were also given to strengthen the calf muscles. Whitman's shoe plates were employed.

A Case of Diabetes in a Child Seven Years of Age.—Dr. David Bovaird, Jr., presented a child, seven years of age, who, three weeks before admission to the hospital, had been noticed to urinate frequently and to pass an unusually large amount of water. He had an extreme degree of thirst, and an unsatiable appetite. He was underweight, poorly nourished, and slightly anemic, and was passing between 3500 and 5500 cc. of urine daily. After keeping the

child under observation for several days to determine the condition under an ordinary diet, he was placed in Dr. Cook's hands for a study of his metabolism on various carbohydrate diets.

Dr. Robert A. Cooke summarized the work done in Dr. Bovaird's case as follows: 1. The rapid disappearance of sugar on a carbohydrate free diet. 2. The very slight increase of acidosis with the sudden change from regular to carbohydrate free diet. 3. The varying utility of the carbohydrate administered in different forms. 4. The rapid elimination of carbohydrates when administered beyond the limit of tolerance.

A Case of Diabetes in a Child Sixteen Months of Age.—Dr. Charles Gilmore Kerley reported this case, which was of interest because of the tender age of the child. When fifteen months of age, the child weighed twenty pounds. The patient had suffered from early malnutrition and had been fed on malt soup. When a little over fifteen weeks old, the mother noticed that the baby was very thirsty, and brought the child to Dr. Kerley. He found that the urine contained three per cent. of suger, as well as acetone and diacetic acid. The child died in two months. This was the youngest case of the kind Dr. Kerley had ever seen.

A Case of Persistent Intussusception Due to an Unusual Cause.—Dr. Charles Gilmore Kerley reported the case of a child which came under observation when seven months old because of constipation and a distended abdomen. The constipation was very persistent, and required the use of laxatives; unless the bowels were moved frequently, the distension would be extreme; when the bowels moved freely, the distension would disappear. There was thus an intermittent distension of the abdomen, with constipation. A rectal examination revealed an intussusception which could be forced up readily with the finger. A tube could be passed into the intussuscepted part and the sac would drain. The condition continued, the abdomen became more distended and, on one or two occasions, quite a collapse was caused because of the pressure of the gas distended intestine upon the diaphragm. Dr. Gant operated seven months ago, entirely relieving the child and curing the intussusception.

Dr. Samuel G. Gant said that it was very easy to verify the condition in the child with the proctoscope; the invaginated portion of the bowel was eroded or in a chafed condition. After examining the child he felt sure that there was both a chronic intussusception and some other mechanical obstruction present. Cases of chronic intussusception were more common than was generally believed. Dr. Gant described the operation he performed. A large fibrous band was encountered which bound the hepatic flexure to the central part of the abdominal wall. This fibrous band was about 1 x ¼ inches wide. The band was divided and then the hepatic flexure of the colon and the sigmoid were anchored to the inner abdominal parietes to overcome the dropping downward of the gut and to prevent a recurrence of the invagination after it had been withdrawn. Dr. Gant stated that he had performed colopexy eighty-nine times for the relief of enteroptosis and chronic invagination in adults and that the results had been almost universally satisfactory.

A Case of Edema of the Glottis Complicating Nephritis in a Child Five Years of Age.—Dr. Joseph C. Roper reported the case of a child, five years old, who was admitted to the New York Hospital with a diagnosis of laryngitis and bronchitis. Up to a few days before admission she was apparently well. She remained in the hospital two weeks. She was believed to suffer from a spasmodic laryngitis complicating a bronchitis. Cultures from the throat showed no diphtheria bacilli. Her condition gradually improved under treatment and she was discharged from the hospital. Several months later, on October 4, the child returned to the hospital with the dyspnea very marked. She had been well until one week before, when she developed a cold and six days later was brought to the dispensary for treatment. On the day following she was brought to the hospital with very marked expiratory and inspiratory dyspnea. A throat culture proved negative. At 2 P. M. she was admitted to the service of Dr. Lewis A. Conner. Intubation was performed with but temporary relief. At 10 P. M. marked expiratory dyspnea appeared following a feeding. The heart gradually weakened and, at 5 A. M. the next morning, without having developed any special cyanosis, the child suddenly died. At autopsy there was found a marked edema of the glottis; the heart was considerably hypertrophied; the left ventricle was slightly dilated and the right auricle and ventricle were distended with blood. The left kidney was markedly atrophied, being represented by a small mass, about 2.5 x 1 cm. The right kidney was enlarged and showed marked parenchymatous changes. The question naturally arose, was this edema glottidis due solely to the renal insufficiency? A negative culture for diphtheria organisms was made on the occasion of the first attack. During the fatal attack a negative culture was made during life. One culture made immediately after death showed a few organisms having the appearance and staining reactions of Klebs-Loeffler bacilli. An emulsion of this mixed culture was inoculated into a guinea pig. This animal died forty-eight hours later of septicemia due to the bacillus mucosus capsulatus. The site of inoculation showed no diphtheritic lesions. Smears and cultures taken post mortem failed to reveal any Klebs-Loeffler bacilli. Sections of the larynx stained by Gram's method with methylene blue showed only cocci and a few short bacilli. The larynx and vocal chords showed moderate inflammatory exudate but no membrane. The deeper layers of the larynx showed some round-celled infiltration.

SECTION ON MEDICINE.

Stated Meeting, Held October 19, 1909.

Dr. C. N. B. Camac, Chairman pro tem.

A Case of Diabetes in a Child Seven Years of Age.—Drs. David Bovaird, Jr. and Robert A. Cooke presented this case. (See report of the Section on Pediatrics meeting, October 14, page 839.)

Dr. T. Stuart Hart asked Dr. Cooke if, in the tables he presented, the weight was that of the rice, or of the carbohydrate contained in the rice, this being, of course, an important point in estimating the comparative tolerance for different carbohydrates. The tables also showed an interesting point to which Dr. Cooke had not referred, namely, that as, under the influences of the restricted diet, the carbohydrate tolerance improved this was accompanied by an improvement in the tolerance for fats. The execretion of β-oxybutyric acid, diacetic acid, and acetone was evidence of the improper oxidation of fats; hence a diminution in the excretion of these bodies (as shown in the tables) indicated the improvement in the utilization of fats. The ammonia estimations, which were supposed to approximately indicate the degree of acidosis, did not, however, in this case corroborate the findings of a diminished acetone-body excretion. Their impression of this fact might, however, be modified if the estimations of ammonia were calculated in actual amounts excreted in twenty-four hours as well as in percentages of total nitrogen.

Dr. J. Rudisch said that what impressed him most in the study of the case was the points brought out by Dr. Cooke, first, that when the twenty-five grams of Uneeda biscuit were given in the morning, usually at seven o'clock, a large amount of glucose was excreted within a few hours, while

the evening urine was sugar free, and, secondly, that when the carbohydrates were given in smaller doses throughout the day the sum total of sugar excreted in the twenty-four hours was greater than in the former instance. These statements might perhaps be best explained by supposing that in the latter case the body was able to convert a larger amount of the carbohydrates into sugar than in the former where the carbohydrates were given at once in a relatively overwhelming quantity, only a part of which could be so converted before excretion. An analogous experiment was seen in the feeding of pancreatic extract in severe cases of diabetes, as well as to dogs from which the pancreas had been removed. The pancreatic extract, by facilitating digestion, made it possible, in the presence of faulty metabolism, to convert a larger amount of the proteins and carbohydrates into glucose.

The Effect of Digitalis Upon the Ventricular Rate in Man.—Dr. T. B. Barringer of New York and Dr. A. W. Hewlett of Ann Arbor, Mich., presented this paper. Of the various cardiac irregularities produced experimentally by digitalis, the earliest to appear in most instances was an occasional omission of ventricular contractions, owing to an interruption of the stimulus between the auricles and ventricles. Somewhat later, or immediately after this, the heart might assume a most peculiar rhythm in which the auricles and ventricles were beating independently of each other. This differed from the ordinary rhythm of complete heart block in that the ventricular rate was not slow, but approached, and, indeed, usually exceeded the auricular rate: so that, for example, one might count sixteen ventricular to fifteen auricular contractions. This rhythm was so common in carefully graded digitalis poisoning that it had become a regular portion of the pharmacological demonstrations given to students at the University of Michigan. So far as they knew, this form of irregularity had never been described in man. Its probable occurrence in the patient reported led them to discuss the effect of digitalis upon the ventricular rate in man. The patient was a teamster, 27 years old, who entered Bellevue Hospital complaining of cough and dyspnea. He had had acute articular rheumatism when he was 12 years old, a suspicious venereal sore when 22 years old, and he had been a heavy drinker up to five months before admission. For two years he had been troubled with shortness of breath on moderate exertion, but in the past two months this had become much more severe and was often paroxysmal in character. He had a loose cough and at times slight fever. There was no edema. The examination showed a well nourished young man suffering from dyspnea. The cardiac dullness was not enlarged, the heart sounds were clear and of normal intensity. The lungs showed a diffuse bronchitis; the left lower axilla showed dullness and diminished breathing sounds, diminished fremitus, and numerous crackling râles. The liver was palpable at the level of the umbilicus. The urine showed a heavy cloud of albumen with a specific gravity of 1,020, and many hyaline and granular casts. After being in the hospital a little less than two weeks he was discharged considerably improved on July 10. On August 3 he was readmitted, complaining of dyspnea. His heart was distinctly enlarged and there was a soft systolic murmur at the apex transmitted to the axilla and back. The second pulmonic sound was accentuated. The pulse was weak, of small volume, and occasionally irregular. The urine was at times negative, at other times it showed traces of albumen. The feet were swollen. He ran a slight but continuous fever. There was a mild anemia. The blood cultures were negative. He died on September 5. There was no autopsy. The clinical diagnosis was chronic myocardial insufficiency with dilatation. During the early part of his second stay in the hospital, his venous pulse was of the usual negative type, the well marked *a* waves indicating normal auricular contractions. The day before he died his general condition had become much more serious and his edema and dyspnea more severe. At times gallop rhythm was heard over the precordium. The venous tracings taken on this day were remarkable in that they showed a regularly recurring cycle of changes. Each cycle required about seven seconds for its completion, and included about fourteen ventricular contractions. At certain portions of the cycle a single, sharp, positive wave occurred in the jugular pulse just after the onset of ventricular systole. Midway between these groups of sharp waves, each ventricular systole was represented on the venous pulse by two waves of almost equal height connected by a more or less distinct plateau. It was evident from the long durations of these cycles (seven seconds) that they were independent of the respirations, for the respiratory rate was constantly about thirty per minute. The explanation of these cycles was to be sought in the interference of two systems of waves which were independent of each other and not quite synchronous. The one system was best represented on their venous tracings by the negative waves which recurred regularly and nearly always distinctly. The other was represented by the apex beats. A comparison between these two showed that the former recurred at a slightly slower rate than did the latter, so that, for example, thirteen of the waves corresponded to fourteen apex beats. There was, therefore, a lack of synchronism between the apex beats representing the systoles of the left ventricle, and the portion of the heart, which caused the waves. It was probable that the negative waves were due to auricular diastoles and that the cyclic variations in the venous pulse were caused by a lack of synchronism between the auricles and ventricles, of such a nature that for thirteen auricular there were fourteen ventricular contractions. On this assumption these cycles in the venous pulse became clear. What came out clearly, when a diagram was constructed to show the relation of auricular and ventricular contractions, was that the single high waves on the venous pulse occurred when the onset of ventricular systole coincided with that of auricular systole. This peculiar rhythm was frequently observed in the later stages of experimental digitalis poisoning. Upon inquiry it was found that the patient had been taking drugs of the digitalis series in considerable quantities over a long period of time. Although the daily amount of digitalis and its allies did not seem excessive, it seemed probable that his irregularity was due to a cumulative action of the drug. If this was true, it illustrated how difficult it might be to ascertain when enough digitalis had been given, for at no time was marked slowing of his pulse observed. This peculiar irregularity was believed to be due to the action of digitalis in increasing the spontaneous ventricular rate. Ordinarily these chambers took their rhythm from the auricles and their tendency to contract spontaneously was held in abeyance. Should stimuli from the auricles fail to reach them, however, sufficient time might elapse for the ventricles to develop their inherent rhythm. In complete heart block they contracted spontaneously and regularly at a rate of about thirty per minute.

Drs. Barringer and Hewlett also reported a case of complete heart block in which an active preparation of digitalis was given in fairly large doses over a considerable period. The patient was a laborer, 60 years old, and had been picked up in the street while unconscious and admitted to Bellevue Hospital. He had used alcohol regularly, to excess at times, and had not had any infectious disease except gonorrhea and a venereal sore. He had an enlarged heart with an accentuated second sound, and a blowing systolic murmur over the apical region. The radial arteries were markedly thickened, and the pulse rate was usually about thirty-three per minute. In the hospital he had a number of typical convulsive attacks. Of the many venous tracings taken, the great majority showed a

complete heart block, although at times there was a partial heart block, or none at all. From this single experience it was impossible, of course, to draw conclusions, though it indicated that moderately large doses of an active preparation of digitalis might fail to increase the ventricular rate in patients with complete heart block, and the authors of the paper concluded therefore that one could not rely upon such an increase as a guard against an overdose of the drug in these patients.

Dr. Lewis A. Conner believed that the interpretations arrived at by the writers of the paper were quite justified. There seemed to be no question but that the tracings indicated a complete dissociation between the contractions of the auricles and ventricles, in spite of the fact that the ventricular rate was much more rapid than was usually the case when such a complete heart block existed. In view of the recognized fact that digitalis could produce in animals such dissociation with a rapid ventricular rate, it seemed fair to believe that the increase in the spontaneous ventricular rate in this particular case was due to the effect of the digitalis administered. Assuming, therefore, that digitalis might be able to increase the ventricular rate in man in complete heart block, it still remained to be proven whether such an effect was desirable. In the present case the patient's condition steadily deteriorated in spite of the fact that the ventricle was contracting as rapidly as one could wish, and his effect upon the ventricle was manifestly an indication of toxic, rather than therapeutic action of the digitalis. It was only by such careful, graphic study of the individual cases as had been made in the present paper that they could hope ever to place digitalis therapy upon anything like a rational basis. They had still much to learn concerning the types of cases in which digitalis was indicated. MacKenzie believed that the useful effects of the drug were seen chiefly in conditions of dilatation of the heart and especially when such dilatation was associated with nodel rhythm. It was evident that when digitalis was not indicated and did no good, it might very well do harm; as, for example, in conditions of disturbed conductivity with a partial heart block, so that the need for a clear appreciation of just what cases were likely to be helped was obvious. They should, therefore, welcome just such studies as those, for it was only by the accumulation of such studies that they could hope to learn the indications for the use of this drug.

Dr. Haven Emerson said that certain facts had evidently been established. Digitalis would cause the ventricles to beat faster than the auricles in digitalis poisoning in dogs. Digitalis had caused the same thing in a patient with advanced myocardial changes. This would have been missed unless the most painstaking analysis of the jugular and apex tracings had been made. The reading of an irregular jugular trace might mean no more than the stethoscope told, or it might on analysis betray essential variations in the irritability, and conductivity of the heart. Such careful technique and study of heart tracings proved more and more profitable as familiarity with the instruments increased, and it should be a matter of pride in a hospital that the necessary instruments were provided for polygraph work, while, as a matter of fact, few hospitals were properly equipped in this respect. The addition of a respiratory record, while adding complexity to a difficult tracing, would avoid all possible criticism as to one of the common causes of uneven jugular waves. This selective action of digitalis upon the ventricle gave an interesting illustration that a drug might exhibit not only the property of susceptibility in different individuals, or in special tissues, but in separate parts of what was essentially one tissue. As an indication of the danger point in the use of digitalis, certainly the absence of the *a* wave in the jugular tracing should prove a more reliable warning than evidences of gastric irritation.

SOME ASPECTS OF ROCKY MOUNTAIN SPOTTED FEVER AS SHOWN BY RECENT INVESTIGATIONS.

THE WESLEY M. CARPENTER LECTURE OF THE NEW YORK ACADEMY OF MEDICINE, 1909.

By H. T. RICKETTS, M.D.,

CHICAGO.

ASSISTANT PROFESSOR OF PATHOLOGY, UNIVERSITY OF CHICAGO.

As your lecturer on this occasion it will be my privilege, a most honorable one, to present a more or less succinct account of an investigation of Rocky Mountain spotted (or tick) fever, which has been under way for more than three years, and which, it is believed, has contributed results of value for a better understanding of the disease, in certain important aspects. Many of the essentials have been described in scattered articles in two different journals, and in two reports which have been rendered to the State Board of Health of Montana. However, such a presentation as I wish to give, involving some new data, a consideration of the natural history of the disease, and certain observations regarding its microbic etiology, may perhaps free me from a possible charge of too much repetition.

History and Occurrence.—It would be interesting if one were able to give a satisfactory history of the disease, bearing on its first appearance among the native Indians and among the white men of the different "infected districts," its early geographic distribution, and the possibility of its having extended into new territories. Knowledge on these points is very incomplete, however, and regarding its antiquity it can only be stated that it was a well-known disease when certain of the older physicians and residents first came into the valley of the Snake river, in southern Idaho, thirty or forty years ago. In the Bitter Root valley in western Montana it is difficult or impossible to learn definitely of cases which appeared prior to the early '80's. Hence it is possible, though by no means to be taken for granted, that spotted fever appeared more recently in western Montana than in Idaho. The Bitter Root valley is separated from Idaho only by the Bitter Root range of mountains, and since spotted fever occurs only on the west slope of the Bitter Root valley, it is conceivable that the disease extended into the latter region from Idaho through the various mountain passes and that it has as yet failed to reach the eastern slope of the valley. It is known as particularly hazardous to visit certain canyons of the Bitter Root mountains during the months of spring.

Its distribution in any one State appears to be very irregular, although it is found here and there over a wide range of territory; in southern Idaho along the course of the Snake river, and in western Montana as stated, at another point in eastern Montana, near Bridger, in the northern and northwestern parts of Wyoming south of the Bridger district, in northern Utah, eastern Oregon, and in ill-defined districts of Colorado and Nevada. In none of these States, however, except Idaho and Montana, has any systematic attempt been made to learn the exact occurrence of the disease.

The irregular geographic distribution is greatly accentuated in certain instances. Thus, in Idaho, for many years the disease was known to occur only on the north slope of the Snake River valley, and if my informants are correct, it has existed on the south side of the valley, in the eastern part of the State, only during the past twelve or fifteen years. Its limitation to the west slope of the Bitter Root valley was mentioned. The various possibilities which may be adduced in the explanation of this peculiarity and the factors which operate for extension, on the one hand, and for its limitation on the other, cannot well be discussed within the limits of this lecture.

No satisfactory estimate can be given of the number of cases which appear annually over this whole territory. In the two infected districts of Montana the number probably varies from fifteen to thirty. Twelve occurred in the Bitter Root valley in 1908 and twenty-six or twenty-eight in 1909. The increased number during the past spring was due to railroad construction, which resulted in the exposure of an unusual number of persons. In 1908 Dr. Edw. E. Maxey of Boise, Idaho, did an admirable piece of work, in which he obtained all possible data regarding spotted fever from the physicians of the State, locating the disease exclusively in the basin of the Snake river, chiefly on the north slope of the valley; 380 cases occurred in Idaho during that year.[1] The work of Dr. Maxey urgently demands repetition in other States.

There is no more striking feature of the disease than its sharp limitation to the months of the spring. In Montana it makes its first appearance in the latter part of March or April, and the last cases are seen at about the middle of June. The spring is earlier in southern Idaho, and corresponding with this the "spotted fever season" begins and closes from two to four weeks earlier than in Montana. The relation of the tick to this peculiar seasonal occurrence will be referred to again.

General Features.—Spotted fever has a history in literature since 1899, when Maxey defined it as follows: "—an acute endemic, noncontagious, but probably infectious, febrile disease, characterized clinically by a continuous moderately high fever, severe arthritic and muscular pains, and a profuse petechial or purpural eruption in the skin, appearing first on the ankles, wrists, and forehead, but rapidly spreading to all parts of the body."[2] I shall not at

this time discuss in detail the various clinical aspects of the disease, but rather refer you to the reports of Maxey,[2] Wilson and Chowning,[3] Anderson,[4] and Stiles[5] for information in this regard. I may only state that, in my experience, variations from the typical type of eruption are encountered rather frequently.[6]

The anatomical changes are not highly characteristic with the exception of the cutaneous phenomena which have been mentioned. Gangrene of the scrotum, prepuce, faucial pillars, and soft palate sometimes occur. Strangely this is met with more frequently in Idaho than in Montana, and the explanation may lie in the difference in the duration of the infection in the two localities. Customarily patients in Montana die before the period when gangrene is likely to occur, whereas in Idaho the large percentage of recoveries gives sufficient opportunity for the development of this phenomenon. Gangrene in both man and animals is a comparatively late symptom. The most striking and constant visceral change is found in the spleen, which is always enlarged and may weigh two or three times as much as the normal organ. Its consistence is rather firm and gives the appearance of a very cellular organ, such as might be caused by a massive proliferation of pulp and endothelial cells. It has none of the soft semi-gelatinous appearance of the typhoid spleen. The lymphatic glands are uniformly enlarged and moderately congested, but in man I have not found them hemorrhagic. The kidneys are swollen and degenerated and the liver is moderately enlarged, congested, and may be fatty. No striking or constant changes are found in the suprarenals, heart, and lungs. The central nervous system shows no alterations except slight meningeal congestion and edema, but these are of a very minor order. In one case I found a lobular pneumonia and the appearance of multiple infarctions of the spleen. The conditions were such that the bacteriology of the case could not be worked out.

The histological pathology is in the hands of Prof. E. R. LeCount.

Severe and Mild Types.—As regards severity, two different types are to be recognized, the mild and the severe, and in this point lies another of the peculiarities of the disease. In western Montana it is almost uniformly of a very severe character, the mortality ranging from about 65 per cent. to about 90 per cent. Children recover with some frequency, adults very rarely. In Idaho, on the other hand, the death rate rarely rises above 5 per cent., and in the 380 cases which Maxey collected in 1908 it was 4.86 per cent. and 3.8 per cent. for the preceding year. This difference would not be so remarkable were it not constant: the spotted fever of Montana has always been severe, while that of Idaho has always been mild. Occasional cases in the latter State go through the entire course of fever without being confined steadily in bed. This feature suggests that the disease in the two localities may not be absolutely identical, but may rather represent varieties, just as we accept paratyphoid fever as a variety of typhoid.

The difference in virulence is also borne out by animal inoculations. Guinea-pigs may be infected with the Idaho disease by the injection of diseased human blood, just as in the case of the Montana disease, and the clinical and anatomical phenomena are the same in both cases. The Montana disease may be kept going indefinitely in the guinea-pig by consecutive passage with a high rate of mortality (about 90 per cent.). On three occasions, however, and with material taken from different patients, I have been unable to maintain the Idaho disease in the same way. In one instance it was carried into the third passage, in another into the fourth, and in the third into the tenth.

In spite of this constant difference, their practical identity is shown not only by the identity of the clinical manifestations, but also by specific immunity tests. Guinea-pigs which have recovered from the Idaho disease are immune to that of Montana, and the converse is also true. It may be that quantitative determinations of the protective and agglutinating power of the two immune serums will show such differences that the two diseases may be considered to stand in a sort of "group relationship" to each other.

Although a satisfactory explanation of this difference may not be possible, it is of interest to note that the spotted fever tick of Idaho differs specifically from that of Montana. Banks has identified the latter as *Dermacentor venustus*. The Idaho tick is also a dermacentor, but its marking are much less distinct than those of *D. venustus*, and it is constantly smaller in size in all its stages, as shown by numerous comparative measurements of the eggs, larvæ, nymphs, and adults. From specimens sent to Banks, he concluded that the species had not been described previously, and he gave it the name of *Dermacentor modestus*. Our experiments have shown that both *venustus* and *modestus* will transmit the Montana disease to the guinea-pig, and *venustus* will also transmit the Idaho disease. So far we have been unable to obtain transmission of the Idaho disease to the guinea-pig by the use of the Idaho tick, *i. e. D. modestus*, except in one instance in which a large number of ticks was involved. It will be for future experiments to determine whether this is due to the comparatively low virulence of the Idaho virus for the guinea-pig, as it exists in *D. modestus;* in other words, whether a larger amount of this strain is required for the infection of the guinea-pig than a single tick of this species is able to inject during its feeding.

It is, of course, possible that the tick plays only a partial rôle in the maintenance of virulence. As indicated later, the disease appears to be maintained in nature by alternating between the tick and some one or more of the native small animals. It is possible that the animals which play this part in Idaho are not identical with those enacting a similar rôle in Montana, and if this proves to be the case, the difference in virulence may depend in whole or in part on the difference in the animals which serve as hosts in the two localities. This may or may not be open to experimental determination.

Theories Regarding the Source of Infection.—In the past various local theories have prevailed, and do still prevail to a certain extent, regarding the source of infection for man. The sharp limitation of spotted fever to the months of spring, suggested to the residents and to many of the physicians that the virus may be obtained from the water which flows down from the mountains during the melting of the snow. It was assumed that this resulted in the flushing out of certain low places which contained decaying vegetation, in which the virus or poison might breed or have its source. In the Bitter Root valley, in Montana, so many of the patients were employees of sawmills, or lived in the vicinity of such mills, that the disease also became associated with this industry. Old and decaying accumulations of sawdust were supposed to contaminate the water,

and many patients give a history of having drunk water from a stream on which a sawmill previously had its site. It is pointed out that there was virtually no spotted fever until the lumbering industry entered the valley.

In spite of a fair degree of plausibility which attached to the water theory, careful examination of the distribution of cases during any one season shows that this does not correspond to any type of water supply. Indeed, one of the characteristic features of the disease, though it is an accidental one, is the rare occurrence of more than one case in a given family during a season, and the number of cases which occur on any one stream during a season is too small to admit of the water theory. Also the rough coincidence of the spotted fever season with that of the melting snow and high water is a misleading one. A few consecutive warm days are commonly followed by a crop of cases of spotted fever in the spring. This, of course, does melt more or less snow, and does cause a rise in the streams, but it is equally efficient in rousing from lethargy millions of ticks which in cooler weather are too somnolent to respond to the presence of a host.

The lumbering industry has indeed been a factor, but only in this, that it took its employees into the timbered country which harbors infected ticks, and caused a general increase in the population of the valley with the consequent exposure of a larger number of persons. The industry of railroad construction did the same thing in 1909. Furthermore, there is no lumbering in southern Idaho, where spotted fever is much more common than in Montana.

The theory that the tick may have a relationship to spotted fever had a fluctuating existence in both Montana and Idaho for some time, but it was not generally credited, and really had its birth with the publication of Wilson and Chowning in 1902.

Previous Investigations.—A laboratory study of the disease was first undertaken in 1902-3 by Drs. Louis B. Wilson and Dr. Wm. M. Chowning, then of the University of Minnesota.[†] In addition to giving an account of the clinical and anatomical phases of the malady, they advanced the hypothesis that the tick is the means of infecting man; described as the cause a protozoon parasite, to which they gave the name of *Piroplasma hominis*, and which they found to have a specific location within the erythrocytes; and suggested that the ground squirrel may be the source of infection for the ticks, basing this hypothesis on the supposed presence of the same parasite in the erythrocytes.

Their work was followed by that of several members of the Public Health and Marine Hospital Service during succeeding years: Anderson, Stiles, and King. Anderson agreed with the essential claim of Wilson and Chowning, namely, the existence of a piroplasma in the erythrocytes of the patients, and also took a stand favoring the hypothesis of transmission by the tick. Stiles, on the other hand, was unable to find the piroplasma, and expressed his disbelief in the tick theory. Wilson and Chowning had no experimental proof of the correctness of this theory, just as Stiles had none to show its incorrectness.

Personal Studies.—The investigations of which it is the purpose to speak were inaugurated in the spring of 1906 with the discovery that the guinea-pig and monkey may be infected with spotted fever through the subcutaneous or intraperitoneal injection of the blood of human patients.* In view of the fact that the disease has been without a known bacteriology during the course of the work, it has been necessary to rely on the clinical course and anatomical changes in the guinea-pig, together with negative bacteriological findings, as criteria for the recognition of the disease in this animal. Since the reliability of the different phases of the work really depends on this point, it is desirable to emphasize that spotted fever in the guinea-pig is a characteristic condition, and that confusion can occur but rarely.

Spotted Fever in the Guinea-Pig.—When the inoculation is accomplished by the injection of virus (diseased blood, and the organs or eggs of infected ticks), an incubation period of from two to five days is followed by a sudden rise in temperature, which may reach 105° or 106° F. (in rare instances 107°) within two or three days, and which persists without remission for a period of from six to twelve days, or until the death of the animal, four to ten or twelve days after onset. A swelling of the scrotum, which begins in the males on the third or fourth day of fever, progresses rapidly, and the overlying skin is soon infiltrated with blood. In white-skinned animals, which are shaved at this time or later, a generalized roseolar eruption, most marked on the back, extremities, and face, can be made out readily. In females the vulva becomes swollen, but exhibits hemorrhages only in occasional cases. Swelling, congestion, and hemorrhage of the lymphatic glands, a more or less massive enlargement of the spleen, which is cyanotic in color, and, in males, marked congestion of the tunica vaginalis and often of the testicles, are the essential anatomical changes, which are encountered with little variation. Commonly the kidneys are swollen and degenerated, the liver swollen, and the suprarenals may show cortical hemorrhages. The serous surfaces, lungs, heart, and central nervous system are never involved, in the absence of mixed infections. As indicated by ordinary culture media, the blood and viscera are sterile.

The "immunity test" is an important and sometimes an essential aid to diagnosis in animals which recover. In the event of mild infection, which has occurred accidentally, or which has been produced deliberately, by modified virus, the fever may be short in duration and moderate in height, and the external hemorrhages may not appear.† In such cases the immunity test, which consists of the injection of from 500 to 1000 pathogenic doses of infected blood, determines whether or not spotted fever was present in the first instance. This active immunity is strong and of long duration, and the offspring of immune females possess a passive immunity which persists for a period of from three to four months.

These data have proved sufficient for the positive recognition of spotted fever in the guinea-pig, and on three occasions they have enabled us to recognize mixed infections which crept into experiment animals in some unknown way.

*The monkey (*Macacus rhesus*), rabbit, horse, and at least five species of small wild animals have a greater or less degree of susceptibility. In all of these except the monkey confirmatory transfers must be made into the guinea-pig in order to prove the character of the infection; hence, for this reason among others, they are of no service for routine experimentation.

†In some successful vaccination experiments a moderate rise in temperature for only one day was all that marked the course of infection. Such animals were thereafter immune.

The transfer of spotted fever to the guinea-pig from human patients in Montana and Idaho has now been repeated not less than fifteen times from as many different patients, and with practically unvarying results. The oldest strain now on hand, representing the Montana disease, has been kept alive by passage in the guinea-pig for three and one-half years, with symptoms and anatomical changes which do not vary from those produced in the first animals injected, and with no decrease in the virulence of the diseased blood. Two other "human" strains have been maintained in the same way, each for approximately a year when they were dropped. Also a strain from naturally infected ticks (*D. venustus*) has now been maintained for six months. Inasmuch as the work has been done with these various strains more or less indiscriminately, it is important to be certain of their unity, and this is shown not only by the identity of the clinical and anatomical phenomena, but also by the fact that each establishes immunity against the others. The integrity of the infection in the guinea-pig was also confirmed by attempts at reinoculation with fresh human virus; animals which had recovered from inoculations with a strain grown in the guinea-pig for a year proved immune to such inoculations, and from the further correspondence of the clinical and anatomical manifestations in man and the guinea-pig, we may be certain that the infection which has been used in the experimentation is identical with human spotted fever. That the disease is an infection rather than an intoxication by non-living material is abundantly demonstrated by the statements just made; the causative agent must be one which is capable of proliferation, in order to survive two hundred consecutive passages in the guinea-pig with undiminished virulence.

Experiments with the Tick.—With the demonstration of the exquisite susceptibility of the guinea-pig it was manifestly possible to proceed to an investigation of the hyposthesis of transmission by the tick.*

The technique of this work was very crude in the beginning, but satisfactory methods were soon evolved, as described in a prior communication.[8] The first problem was one of simple transmission, namely, is the tick (*D. andersoni* of Stiles, *D. venustus* of Banks) able to transmit spotted fever from the sick to the healthy animal by means of its bite? The initial successful results, obtained with a single female and later with a single male (1906), have been repeated, I should estimate, not less than two hundred times in the course of various experiments conducted in the field and home laboratories. There is, indeed, no difficulty in obtaining it. It is only necessary to permit a tick to feed on a diseased guinea-pig for several hours to a day, and then to transfer the arachnid to a healthy animal as soon as it can again be induced to bite.

The exact duration of feeding required for infection of the tick has not been determined. This must vary a good deal. The tick is a slow feeder. From fifteen to twenty minutes are required for the hungriest and most vigorous to attach itself firmly, and without firm attachment by means of the palpi, feeding is impossible. In other instances the process is much slower, and after two or three days of attachment there is little evidence of the ingestion of blood.

In so far as we have determined, the incubation period in the tick is brief, and, perhaps, is represented only by the time required for the distribution of the virulent organisms throughout its body and eventually into its salivary glands. In a number of instances the tick proved virulent immediately following its removal from the infected animal. In one exceptional experiment, transmission could not be obtained until nearly two weeks following the infected feed.

Likewise the minimum duration of the bite required for inoculation probably varies a good deal, depending on the vigor of feeding. Dealing with ticks whose infection had already been proved by longer feedings, transmission resulted several times from ten-hour exposures, and recently from a feed of less than two hours.*

The mechanism of transfer would seem to consist of the injection of the salivary secretion, laden with virus, into the cutis of the host. By injecting into the guinea-pig separate triturations of the salivary glands and alimentary sac of the infected tick, the presence of the virus in these tissues was shown in 1907. It seems that the tick must undergo a generalized invasion by the virulent organisms, from the intestine as a point of departure, with their eventual localization in the salivary glands. The hereditary transmission of the disease, involving the presence of the virus in the oviduct and germ cells, is a further indication of this generalized infection. That a toxic secretion is injected at the time of feeding is indicated by the intense local reaction which follows the bite of even the normal tick. There is, indeed, no difference between the bite of the normal and the infected tick. The spotted fever virus does not produce a local cutaneous or subcutaneous reaction.

Inheritance in the Tick.—In the summer of 1907 three additional points were determined regarding the relationship of the virus to the tick, namely, the occurrence of hereditary transmission, the possibility of "stage to stage infection," and the existence of naturally infected ticks. The first point was demonstrated by permitting the offspring of infected females to feed on normal guinea-pigs, and the development of spotted fever in the latter signified the transmission of the disease from the female to the larvæ through the medium of the germ cell. The frequency with which hereditary transmission occurs has an important bearing on the natural history of the disease, particularly on the means by which it is maintained from year to year, and for more accurate information in this regard, the subject was again taken up in the winter of 1907-8 with

*The infective dose of diseased blood drawn on the third day of fever in the guinea-pig is frequently as small as 0.001 c.c., when injected intraperitoneally into a fresh animal.

It is interesting to note that the first experiments which were performed with the intention of determining a possible relationship of the tick to spotted fever were done on the human subject, and have not been formally reported by the authors. I have referred to this in a former article, and here may only repeat that Drs. McCalla and Brereton of Boise, Idaho, infected two individuals successively by the bite of a tick which they had removed from one of their patients. Naturally, the consent of the subjects was obtained, which in this case was not difficult on account of the mild nature of the disease in Idaho. The experiments of McCalla and Brereton followed the publication of the tick hypothesis by Wilson and Chowning, and they were unknown to me until after the larger part of my work with the tick had been done.

The first transmissions of spotted fever in the guinea-pig by means of the tick were undertaken and reported almost simultaneously by Dr. W. W. King of the Public Health and Marine Hospital Service and by the writer.

*The problem of time relationship is now the subject of further study by Mr. J. J. Moore.

the assistance of Dr. Maria B. Mayer. In the neighborhood of thirty females were infected and the virulence of each was proved by means of a feed on a normal guinea-pig, after which they were put aside for the laying of eggs and the hatching of the latter. Broods were obtained from only eighteen of this number, and of the eighteen only nine proved capable of infecting the normal guinea-pig, giving us 50 per cent. of hereditary transmission. This percentage is greater than that obtained in either earlier or later experiments, and it seems to be a safe conclusion that under natural conditions hereditary transmission does not take place from more than 50 per cent. of the infected females.

The practical significance of this result is seen when one attempts to answer the query: How is spotted fever maintained in nature? The occurrence of hereditary transmission explains perfectly how the disease is kept alive from one spring to the next, but does not explain its permanent maintenance since not more than 50 per cent. of the infected females transmit the disease to their young. Assuming that the total number of ticks in an infected region remains the same over a period of years and this condition appears to be approximated in the Bitter Root valley, a 50 per cent. reduction in the number of hereditary transmissions for each succeeding year would, in the course of time, spell the extermination of the disease among the ticks. There is no evidence, however, to show that spotted fever is decreasing. It would seem that its very existence at this time signifies a prolonged previous history, and that there exists in nature a mechanism for the annual replenishment of the virus among the ticks, to offset the reduction (50 per cent. or greater) which takes place every year. I shall have occasion to speak of this further when considering the relationship of native animals to spotted fever and the source of infection for the ticks.

"Stage to Stage Infection."—Still another phase of the relationship of the virus of spotted fever to the tick would seem to be of importance for the maintenance of the disease; this relates to the occurrence of "stage to stage infection." In the summer of 1907 larvæ from uninfected females were permitted to feed on guinea-pigs which had been inoculated with spotted fever. After they had molted into the next active stage (nymphal) they were placed with normal guinea-pigs; the development of spotted fever in the latter, after being bitten by the nymphs, proved that the organisms when taken in by the larvæ, retain their life and virulence, until the succeeding active stage is reached. In a similar way it was demonstrated that the nymph which feeds on diseased blood is still able to transmit spotted fever when it reaches the adult stage, some weeks later.

"Stage to stage infection" would be of little significance for the maintenance and spread of spotted fever were it not for the habit which *Dermacentor venustus* and *D. modestus* possess, of dropping from the host for the process of molting.* To assume a case, larvæ which have inherited their spotted fever may infect a ground squirrel; dropping from this animal in order to molt, certain of them, after reaching the nymphal stage, may reach a hitherto uninfected ground squirrel, or a rock squirrel, and convey the disease to the latter; and this event may again be repeated after the adult stage is reached. Thus it is possible for a single tick to infect two or three different animals in the different stages of its development. The habit of dropping also affords opportunity for extension of the disease among the ticks. Nonvirulent larvæ and nymphs, feeding on a susceptible animal in company with infected ticks, may well derive the disease from the animal after its infection is established, and they in turn after molting and seeking further hosts may cause additional extension in the same way. Hence, it is manifest that the facilities for extension are much greater, in view of the habit of "dropping" than they would be if the tick remained on its original host during its entire development.

From what has been said it may be inferred that the ticks in question have a multiplicity of hosts. They are known to occur naturally on at least seventeen of the domestic and wild animals of the Rocky Mountains (horse, cow, dog, swine, sheep, elk, deer, mountain goat and sheep, bear, ground squirrel, pine squirrel, rock squirrel, ground hog, chipmunk, mountain rat, and the so-called rock rabbit), and experimentally they feed readily on the guinea-pig, rabbit, and monkey.

Naturally Infected Ticks.—As proof of the etiological relationship of the tick to spotted fever, I have cited the experiments of McCalla and Brereton, in transmitting the disease from man to man, and my own work demonstrating the carrying power of the tick, and the intimate relation of the virus to the tick, as illustrated by hereditary transmission and stage to stage infection. To these may be added the almost unfailing history of recent tick bites in the cases of human infection.* With all these data, however, it may still be argued with some show of reason, that these conditions are accidental, that the mere fact that the tick has the carrying power does not constitute proof that man acquires his infection from the tick. Furthermore, to remove an infected tick from a human patient and prove its virulence does not improve the character of the proof, since the critic may say that the tick derived its infection from the patient, rather than the converse.

Appreciating both the pertinence and the improbability of this conception, it seemed that the situation demanded the discovery of naturally infected ticks. This was undertaken successfully in 1907. Several hundred ticks from an "infected district" were allowed to feed on guinea-pigs in groups of from thirty to fifty. One of these groups produced spotted fever in its guinea-pig, and the diagnosis was verified by repeated passage and immunity tests. During the past spring it seemed desirable to repeat this observation. Ticks were collected from Lo Lo valley, which is tributary to the Bitter Root valley and sent to Chicago, where Dr. Mayer conducted the tests, placing the ticks with guinea-pigs in groups as in the previous experiments. In this instance infected ticks were found in two of the groups, and a strain of spotted fever derived in

*This is the custom of most species, but some, as *Margaropus annulatus*, which carries Texas fever, remain on the host for both molts. The latter, after reaching a host as larvæ, remain with it until the adult stage is reached, and, indeed, until the female is ready to drop and lay her eggs. Hence, even if stage to stage infection occurs in this instance, it can have no great significance for the extension of Texas fever.

*As stated in reports to the State of Montana, the failure to find a tick on the patient or evidence of a recent tick wound, provides no evidence of the absence of a tick bite. A few hours' feed only is required for infection, and a tick may feed and escape or be brushed off accidentally and the individual himself have no knowledge of the bite. Tick wounds situated on the scalp or perineum may well escape very careful search

this way is still being carried on by the method of passage in the guinea-pig.

With the discovery of naturally infected ticks, it would seem that the requirements for proof of the relationship of the tick to the infection of man have been met as fully as it is possible to meet them.

Seasonal Relations.—As I have stated elsewhere, the peculiar limitation of spotted fever to the months of spring depends on two facts in relation to the development and habits of the ticks involved: First, that the cycle of development is annual, and second, that only the adult ticks are found as parasites of man,* and adult ticks are to be found only in the spring, or roughly so. One may, indeed, find occasional adults in February or the latter part of January, or, on the other hand, as late as August or September. High in the mountains they are found later in the summer than in the lower valleys. Presumably, this is on account of the lower temperature in the former localities, which favors both a late development, and a prolongation of life after the adult stage is once reached. Such observations are exceptional, however, and it remains true that the appearance and activity of the adult begins some time during the latter part of March or the first part of April, the exact time depending on the occurrence of warm days, and that they are not commonly seen after the middle of June. We may be quite sure that the temperature of the region is the most potent factor in determining this rather sharp annual cycle. From experience gained in laboratory cultivation, and by observations on the stock and wild animals, we may fix the egg-laying period in nature in the latter part of the spring and the early part of the summer. During the summer larvæ and nymphs are found on the small wild animals in large numbers, and it is probable that many of the nymphs have had their feed and dropped from their hosts before the onset of cold weather. In several instances, however, large numbers of feeding nymphs have been obtained from horses in December and January, hence it is probable that the nymphal development is in progress during the most of the winter. Those which drop from the hosts late in the autumn probably spend the entire winter in the resting or molting stage, which they complete on the advent of warmer weather. Little progress is made in molting during the winter. Enlarged nymphs have been kept in the laboratory at a temperature of about 10° C. for nine months without molting, but when removed to the temperature of the room, the process would go on to completion in about the usual time. The enlarged nymphs which drop from their hosts at any time during the winter must wait for the warm weather of spring before they can cast their skins and appear as adults.

Source of Virus for the Tick.—The observations in relation to hereditary transmission in the tick indicate, as stated previously, that it is necessary to assume some extraneous source of infection for the tick in order to explain the maintenance of the disease.

At the outset it would be natural to inquire whether man can play the same rôle in the maintenance of spotted fever as he does in that of malaria and yellow fever, and as he possibly does also in the maintenance of human tick fever of South Africa. Without going into a full discussion of all the conditions which would seem to render this impossible, the essential reasons for this conclusion may be given as follows:

Ticks which are naturally infected have no relation to the habitation of man; they are wood ticks, not house pests, and are not found in the houses except as they are brought in accidentally on the clothing. The conditions are very different in the relation of *Ornithodorus moubata* to South African tick, or recurrent fever. The latter have the habits of the bedbug to a large degree, secreting themselves in the house during the day and coming out at night to feed on the inmates. In this case man may well be the common or only source for the fresh infection of the carriers. For man to be concerned in the maintenance of spotted fever it would be necessary to assume that ticks which were hitherto normal must feed on him during the course of his illness, and that the females must either mature on him directly in preparation for the laying of eggs, or, after leaving him, must subsequently find some other host on which it may mature. One who has seen the enormous size which the matured female attains, and who knows that a continuous feed of not less than a week or ten days is required for this degree of development, can hardly conceive of its occurrence on a patient who has been stripped of clothing and is confined in bed. Spotted fever patients are invariably looked over carefully for ticks, and it is a safe conclusion that those which are found are destroyed with little ceremony. Regarding the possibility that a tick after once feeding on a patient may escape and subsequently find another host on which it may mature, this must be admitted as a rare possibility, or better as an extreme improbability. The tick travels slowly, covers very short distances, and does not readily find a second host. On account of the virtual impossibility of a female maturing on man, we should have to assume that the second host in this case would be an animal rather than another human. The dog, and perhaps the cat (?), exist as the only reasonable possibilities in the way of such a second host, and they alone render the occurrence under consideration a rare possibility. Given even the matured and infected female, the likelihood of the offspring being infected is not more than 50 per cent., and, furthermore, the chances which operate against the development of the progeny of any one female to the succeeding adult stage are very heavy. Hence, for these various reasons the process mentioned virtually drops out of consideration as a means for the maintenance of spotted fever.

The Study of Small Wild Animals.—Holding to the correctness of the conclusion just stated, it seemed necessary, in a search for the source of infection for the ticks, to turn to its more general food supply, namely, to one or more of the domestic or wild animals on which the arachnid feeds more or less extensively. The question may be raised as to whether it is justified to exclude the vegetable kingdom from an investigation of this character. In answer one can only say that the probabilities of the case seemed to justify such an exclusion. It is the general and firm belief among entomologists that such ticks live exclusively on the blood of animals, and that the anatomy of their mouth parts permits of no other type or mechanism of nourishment. I have undertaken no work to determine whether or not the life of ticks may be prolonged by keeping them in the presence of various types of living, dead, or decaying vegetables, or, for that matter,

*Only in two instances have I learned of larvæ and nymphs feeding on man; children were concerned in both instances.

with dead or decaying animal tissues. In a fairly extensive experience, however, they have never been observed in the position of feeding on such vegetables as are kept with the animals in the tick-proof cages, namely, carrots, cabbage, dandelions, and clover. Concerning the possibility that they may feed on dead or decaying animal matter, it can only be said that ticks, as a rule, make haste to leave the body of an animal on which they have been feeding after the death of the latter. As a determining influence, moreover, we had before us the demonstrated fact that the tick readily acquires spotted fever by feeding on the blood of an infected animal, and it seemed rational to assume that it would acquire the disease in a similar manner under natural conditions.

Hence, a campaign was outlined, which had as its object a study of the various animals which serve as natural hosts for the tick—a campaign which has not yet been brought to a conclusion, but which has yielded results so suggestive in their character as to furnish an ample reward for the labor and difficulties involved.

Certain types of animals were eliminated from the study for what appeared to be justifiable reasons. Because of the limitation of spotted fever to the Bitter Root valley, in so far as western Montana is concerned, it was decided to postpone the study of animals which wander widely. Hence deer, elk, bear, birds, and animals (mountain goat and sheep), which continuously remain remote from human habitation were omitted from the list, at least for the time being. Also, because of the demonstrated resistance of the horse (relative resistance), ox, sheep, and the fowl, the domesticated animals were not subjected to further study for the purpose under discussion.

Just one definite clue served to indicate the type of animal which, it appeared, should be selected for the first experimentation. This concerns the segregation of spotted fever not only in the Bitter Root valley as contrasted with adjacent districts in which the ticks and animal life are identical, but also its localization to the west slope of the valley, and even to particular foci on the west slope. On the basis of this consideration it would seem that an animal to be concerned in maintenance must be one which has a tendency to a more or less permanent abode, one which does not wander widely from its habitation from year to year, hence one which would not be likely to disseminate infected ticks over a large area.

The ground squirrel (a spermophile), ground hog or woodchuck, the rock squirrel, the chipmunk, the pine squirrel, rock-rabbit, mountain rat, and perhaps the three species of rabbit found in the district (cotton-tail, snow-shoe, and jack rabbit) were considered as meeting this requirement more closely than other species.

Briefly, the plan was first to determine the susceptibility of these species as it might be indicated by the injection of virulent blood; second, with those which were found to be susceptible by the method of injection, to attempt infection by means of the bites of ticks of known virulence; third, to perform "tick cycle" experiments, by which is meant the production of the disease by means of the tick, while at the same time permitting normal ticks to acquire the disease by feeding on the animal during the course of fever; fourth, and last, to attempt to discover individual animals in nature, which were either suffering from spotted fever at the time of observation, or which had survived an infection at some previous time. The last point was to be determined by means of immunity tests, provided, of course, that the previous experimentation should show that one attack in the various species confers lasting immunity. It has not yet been attacked experimentally.

It is to be understood that in the study of the first three points, the animals used in the experiments were taken from localities in which spotted fever had not been known to occur.

The first experiments with the ground squirrel were perplexing. It had been anticipated that a rise in the temperature of this animal would serve as a guide to the occurrence of infection, as it does in the case of the guinea-pig, rabbit, and monkey. The results, however, were very inconstant in this regard. In four out of thirteen animals inoculated, four had absolutely no fever. The shortest febrile period observed was one day, and it persisted no longer than four consecutive days in any of them; in four animals it lasted for three days, and in another for two. "The incubation period varied from one to five days. It was five days in one animal, four days in two, three days in four, two days in one, and one day in one animal. During the incubation period the temperature varied between 100° and 103°, being for the most part below 102.5°. One observation was as low as 97.8°. After the cessation of fever the temperature returned to about what it was during the incubation beriod."[9] But one of the animals inoculated died, and at autopsy the only discoverable change was a pronounced enlargement of the spleen, as compared with controls which were killed for the purpose of comparison. From this animal, and also from one other which exhibited distinct fever, transfers of blood were made into the guinea-pig, and in both instances the latter developed typical attacks of spotted fever, as shown by the fever, hemorrhages into and gangrene of the scrotum, and the changes in the spleen and lymph glands seen at autopsy.

The series showed the possibility of infecting the ground squirrel with spotted fever, but it seemed necessary to conclude either that the susceptibility of the different individuals is not uniform, or that the temperature which follows injection cannot be taken as an index of infection.

With the hope of obtaining information regarding the last point, "the temperatures of a number of normal gophers were taken for several consecutive days in order to learn its natural variations. It was found to be very inconstant and the irregularities were not always to be accounted for. When the weather was cool, as in the mornings, it was common to observe a low temperature, and for several days it might remain in the vicinity of 97° or 98° F. At other times it was low when the outside temperature was too high to account for the condition. That of the normal animal rarely exceeded 102.5° or 103° F., and it was concluded that this would represent approximately its temperature when in a state of normal activity, and with metabolism at par. The fact that the gopher is a hibernating and a semi-cold-blooded animal, no doubt is responsible for many of these variations. When in actual hibernation the temperature in three instances was so low that it did not register on the clinical thermometer. It has been observed, also, that there are individual variations in the tendency to go into the somnolent state, that even at the warm temperature of the laboratory

one may be so somnolent that he can be taken out and handled without awakening, while others will be quite active. It seemed more probable, therefore, that the temperature of the gopher is not a good index of his infection rather than that 30 per cent. of the species should be naturally resistent to the disease."

During the following spring and summer (1908) this was proved to be true. Of a series of squirrels which received quantities of virus from the guinea-pig varying from 0.02 c.c. to 3.0 c.c., and which showed the greatest irregularities in temperature, following the injections, every one acquired spotted fever, the diagnosis being established by the injection of blood from each of the animals, at the proper time, into normal guinea pigs.

It may be mentioned as a point of incidental interest that a *relative fever* developed in a large percentage of the ground squirrels. If the temperature of a particular animal had been found in the neighborhood of 98° or 99° for several days, it would commonly rise to a height of 101° to 103° during the customary febrile period, the latter being scarcely above that of the normal active animal.

The experience taught a new point in technique, namely, that for the positive recognition of spotted fever in the ground squirrel it is necessary to carry the inoculation back again from the latter to the normal guinea-pig. Eventually this step was adopted as a uniform procedure in the work with other small wild animals.

Following this plan of experimentation, the ground squirrel, ground hog, rock squirrel, chipmunk, and mountain rat were found to be susceptible to the innoculation of the virus of spotted fever, as represented in the blood of the infected guinea pig on the third day of fever. The first four species were also found to be susceptible to the bite of single virulent adult ticks, the infectivity of which had been proved previously on normal guinea pigs. It was not possible at the time to study the susceptibility of the mountain rat to the bite of the infected tick.

It is of theoretical and practical importance to know whether spotted fever is an acute self-limited infection in the animals under consideration, or whether it may exist in a chronic form. If it were sufficiently chronic, lasting for a year or more, as in the case of certain protozoon diseases, maintenance could be accomplished without the aid of inheritance in the tick. Inasmuch as the latter does occur the only evident influence of chronicity in the animal would be a more massive infection of the ticks of the locality. Investigations have shown, however, that the number of infected ticks, in comparison with the whole, is very small—so small indeed that this fact alone would seem to be a strong argument against chronicity in the four-footed hosts.

Two general arguments also speak for acuteness in the small wild hosts: first, that in the other animals which have been studied carefully, and in man, the disease is acute and self-limited; second, that after recovery protracted (probably permanent) immunity is established against reinfection, and the serum of such animals possess protective antibodies in considerable concentration—much more than is found in any known chronic disease.

In only two of the wild animals has the subject been studied specifically, the ground squirrel and the rock squirrel. After they have recovered the blood is free from virus, as shown by transfers into the guinea pig, and they resist attempts at reinoculation. One-half c.c. of the blood of the immune ground squirrels was found to protect the guinea pig against approximately 1000 pathogenic doses of virus, the blood of the normal squirrel having no protective effect. The possible presence of the virus in some of the internal organs of these animals after recovery has not been investigated. The concentration of antibodies in the blood would seem to preclude this. It is not found in the spleen of the guinea pig and monkey after recovery.

It is manifest from previous statements that spotted fever in the tick is very chronic. The relation of the disease to the tick, indeed, does not differ from that of various microparasites to their insect carriers in this respect.

"Tick Cycle" Experiments.—The "tick cycle" experiments represented an attempt to duplicate what was assumed to be a step in the maintenance of the disease in nature. Individual ticks, rather than groups of ticks, were dealt with, and the following steps were involved:

First, the individual testing of virulent ticks on separate guinea pigs in order to prove their infectivity before beginning the experiment; second, the testing of the supposedly normal ticks on guinea pigs to insure their freedom from the virus; third, the attachment of a single infected tick to the ear or head of the small wild animal, permitting the former to feel for a period which was known to be sufficient for the production of the disease; fourth, after the elapse of an interval corresponding to the established incubation period, to draw blood from the heart of the experiment animal, and inject it into the guinea pig for the purpose of determining the existence or nonexistence of spotted fever in the wild animal; fifth, the attachment of one or more normal ticks to the latter as soon as the incubation period has passed; and sixth, the testing of the latter on normal guinea pigs in order to determine whether or not they had acquired the virus during their feed.

There were many failures and embarrassments due to the accidental death of valuable ticks, or of animals, or to failure to do the right thing at the right time in all cases; but eventually positive "tick cycle" experiments were obtained with the ground squirrel, ground hog and rock squirrel. With the delicate little chipmunk the cycles were broken in character. Several times this animal was infected by the bite of virulent ticks, and we were successful in transferring the disease from the chipmunk to the tick, following the inoculation of the former by means of the syringe. In the "cycle" experiments, however, the intermediate step of bleeding from the heart proved fatal in nearly all cases, which, of course, prevented the completion of the experiment. Nevertheless, the broken character of the experiments with the chipmunk does not materially impair their significance.

These experiments would have little justification were it not for the fact that the animals mentioned are utilized as hosts by the tick at one stage or another of its development. Particularly on the ground squirrel, rock squirrel and pine squirrel (the last not yet studied), larvæ and nymphs have been found in great abundance, and on the other animals mentioned, to a less extent. That adult ticks are found less commonly, indeed rarely in my experience, on these animals than the earlier stages, in no way invalidates the experiments, which were performed with the adults, since an abundance of experience shows that the larvæ and nymphs do

not differ from the adults in their ability to acquire and transmit spotted fever. We may only bear in mind the possibility that more than one larva may be required for the production of the disease,* whereas, a single nymph or adult is sufficient.

Maintenance.—In accordance with the results and deductions which have been outlined, it is conceived that spotted fever is maintained as follows: A certain percentage of the female ticks which have acquired the disease as a consequence of feeding on animals, the latter having been infected by other ticks, transmit the disease to their offspring through the egg. The new generation during the process of feeding transfer the virus to certain of the susceptible small wild animals (ground squirrels, rock squirrels, chipmunks, ground hogs, and perhaps others), and this may take place during either the larval, nymphal or adult stage, hence at various times of the year. During the infection of the wild animal it is required that hitherto normal ticks, either as larvæ, nymphs or adults, acquire the disease by feeding simultaneously with, or shortly after, the feeding of the infected ticks. Regardless of the tick's stage of development at the time it acquired the disease, the virus is retained into the adult period, and in certain of the females reaches the germ cells and again appears in the next generation. The infection of man is an unessential incident for maintenance, and depends on the occasional and accidental bite of the infected adult tick.

I shall not discuss the bearing which these results have on the control and the eradication of the disease further than to say that this work naturally should take two directions, one having as its object the destruction of the ticks in proximity to human habitation following methods which have proved successful in the campaign against Texas fever, and the other leading to the extermination of the susceptible wild species of animals, a procedure which also has as a consequence the curtailment of the food supply for the ticks. Detailed recommendations embodying these points have been made to the State Board of Health of Montana.

Microbic Etiology.—Inasmuch as rational methods for the control and eradication of spotted fever depend on an accurate acquaintance with the means by which man is infected, and the agencies through which the disease is maintained in nature, it is fortunate that these questions could be investigated without any knowledge of the microorganism which causes the disease. Yet so much theoretical, and perhaps practical, importance pertains to the recognition, and particularly to the cultivation of the causative agent, that this part of the problem has never entirely dropped out of mind. Following many failures, further study was often deferred until other lines of work which promised solution could be disposed of.

With the knowledge that the tick is the agent through which man is infected, one turns naturally, and first of all, to some other diseases of known etiology which are also carried by one or another species of tick, at the same time keeping in mind the dangers of generalizations and analogies. When spotted fever was first studied ticks were known as the carriers of piroplasmas only. On the other hand, since 1903, it has been definitely shown that ticks are the medium of conveyance in at least three diseases which are caused by spirilla, the spirillosis of fowls (Marchoux and Salembini), South African tick fever of man (Dutton and Todd, and Koch), and a disease of cattle in South Africa (Theiler).

With these analogies in mind, and animated also by the conflicting opinions of Wilson and Chowning on the one hand, and Stiles on the other, a careful search has been carried on for both piroplasmas and spirilla, but with absolutely negative results in both cases. If it is fair to judge from the known infections with piroplasmas and spirilla, it would seem that the recognition of these organisms should not be attended with great difficulties, particularly since the introduction of the Romanowsky method of staining, with the various convenient modifications. In the case of the known piroplasmoses the blood is often heavily infected, with many parasites in a single field, and even the most minute species, as *Piroplasma parvum* in the cattle of South Africa, are of such size in relation to the erythrocytes that they could not escape detection in prolonged microscopic studies which were carried on during all stages of the disease, with both the blood and the various internal organs. Such studies were entirely negative with both fresh and stained material, and after many months of study in which fresh material was always at hand the conclusion was reached that spotted fever either is not caused by a piroplasma at all, or if it is, that the organism is extremely minute (ultramicroscopic) and not susceptible to microscopic demonstration.

There are also some general considerations which suggest strongly that spotted fever is not a piroplasmosis. In the first place there is no massive destruction of the erythrocytes in either man or the guinea-pig, the number of which does not fall below a level commonly seen in various febrile infections. There is no hemoglobinuria, such as is seen in many piroplasmoses, and the degree of icterus is not more than frequently occurs in different fevers of bacterial cause, nor is the blood pale and watery. Further, the facts that spotted fever in man is invariably an acute self-limited disease, and that the serum of man and animals after recovery possess protective antibodies in rather high concentration, are not in harmony with a piroplasmatic etiology.

The results of the search for spirilla were similar. In relapsing fever, in the South African tick fever of man, and in the spirilloses of animals, the number of organisms in the circulation is often very conspicuous. In spotted fever, on the other hand, exhaustive search of the blood and tissues in all stages of the disease, and painstaking examination of the tissues and eggs of infected ticks, has failed to reveal the presence of spirilla. Here again it must be concluded that if spirilla are present they are so small as to justify the assumption that they would be ultramicroscopic or filterable.

Similarly the possibility of a leucocytic parasite has always been kept in mind, but such forms have not been observed

From time to time various experiments were performed with the hope that some light might be thrown on the character of the organism. The virus was found to have a fairly uniform distribution in the various body fluids and organs. It proved not to be an exclusive parasite of either the red or white cells of the blood, but was found in approximately the same concentration in the lymph and serum as in the full blood. Its resistance to heat and light and plasmolysis* was such that no conclusion

*In testing the virulence of eggs, five is the smallest number which so far has proved capable of infecting the guinea-pig.

*Experiments conducted in association with Dr. P. G. Heinemann.

could be drawn regarding its bacterial or protozoon nature. None of these indirect methods furnished evidence of particular value relating to the character of the organism.

A generalization frequently made in former years emphasized the hypothesis that all diseases which are transmitted habitually by insects are probably due to protozoon parasites, the assumption resting on facts which were known in relation to many insect-borne diseases, as malaria, piroplasmosis, the malaria of the birds, and more recently, trypanosomiasis. Plainly, however, the newer developments regarding the relation of the flea to plague, and the tick to the relasping fever of South Africa, both bacterial diseases, remove the ground for the generalization, and in facing a new disease of this type to-day, the possibility of a bacterial rather than a protozoon etiology demands unprejudiced consideration. If, indeed, one were to resort to generalization in the case of spotted fever, it may well be in favor of a bacterial instead of a protozoon parasite, because of the chronicity and low grade of immunity which pertain to the known protozoon infections. Even this, however, cannot be ventured with justifiable assurance because of the number of diseases whose etiology is still unknown.

Interest in the microorganism has been sustained by the results of filtration experiments. Repeatedly, virulent serum, both when concentrated and greatly diluted, lost its infective power after being passed through Berkefeld candles. It is, of course, conceivable that the filter may have been more or less occluded by the large number of albuminous particles in the serum, a condition which would interfere with the passage of the organism through the filter. Later, when dealing with virulent eggs from the tick, the filtration experiment was repeated under more favorable conditions. In one instance, two hundred eggs were crushed and thoroughly shaken in five cubic centimeters of salt solution. The albumin was so scant that even a faint degree of opalescence could not be detected in the salt solution. This was filtered and the candle washed with five additional cubic centimeters of salt solution. Of the filtrate a quantity representing one hundred and fifty eggs was injected into one guinea-pig, and another, representing fifty eggs, into a second. Neither of the animals developed spotted fever although five, ten and fifteen of the unfiltered eggs produced the disease in controls. This was accepted as proving finally the non-filtrability of the virus through the ordinary, unmodified Berkefeld candle, and is further evidence that the organism is of such size that it should be seen with the microscope.

Following this brief account of negative findings reference may now be made to a bacillus which has been found in association with the disease under interesting circumstances. In the early part of the studies a diplococcus-like body with an eosin staining intermediate substance was encountered, first in the blood of an infected monkey. Further examination disclosed the presence of similar bodies in the blood of infected guinea-pigs, and later in man, and it came to be the common experience that they could be found in any preparation of infected blood during a search of not more than a half hour's duration, the specimens being stained with Giemsa's solution after fixation in absolute alcohol. The morphology varies somewhat regarding the size and proximity of the two staining bodies, and even small bacillary forms are encountered. In spite of this constant observation the conditions were such that a positive interpretation was impossible merely on the basis of the microscopic findings. The forms are very minute and often appear as a pair of granules which might arise from a disintegrated leucocyte or from a fragmented nucleus. As rendering the latter interpretation plausible, disintegrating leucocytes frequently occur in the blood, particularly of human patients, and in such examples small globules of chromatin may sometimes be found in proximity to the injured cell. Further, my own attempts, and the attempts of Mr. P. G. Heinemann, to cultivate an organism of this or any other character from the blood of patients and animals had been fruitless.

Some months ago it was possible to take up seriously a long-deferred line of investigation, namely, a study of the organs and eggs of the tick with the hope that the microorganism might be present in such concentration or form that its identification would be possible. The disease being hereditary in the tick, it seemed that the freshly layed eggs might be a most favorable medium for search as in South African tick fever, one in which there would be comparatively few opportunities for confusion. The first preparations from a batch of virulent eggs showed the presence of an astounding number of organisms which for the most part have the form of minute polar staining bacilli. Frequently, two or three are attached end to end, and the staining poles give the appearance of a chain of four or six cocci. In the eggs, as a rule, the amount of intermediate substance interposed between the poles is comparatively large, the stained masses being rather widely separated. Frequently, however, the poles are more closely approximated, such forms resembling closely the "diplococcoid" bodies seen in infected blood.

Still other bacilli are found which stain solidly, and they too are often in pairs (diplobacilli). In the latter it appears that the staining substance has not yet become segregated into the poles of the organism. Intermediate forms in which the chromatin of the two ends communicates at one or both borders of the cell substantiate this belief. When specimens from a batch of eggs are examined from day to day a change takes place in their predominating morphology, as the cells of the embryo tick multiply. The sharply marked bipolar forms with the wide intermediate substance gradually become fewer and fewer, and the presence of some which have become abnormally large and swollen indicates that many are in process of dissolution. On the other hand the number of smaller "diplococcoid" forms undergoes an increase, and many of them eventually appear in groups within the cytoplasm of the embryonic cells of the tick. The growth of the latter, however, hardly compensates for the disappearance of the larger bipolar forms, and the impression is gained that the total number of organisms has undergone a decrease. In spite of this change the virulence of the eggs does not decrease. In one batch in which five eggs produced infection when freshly layed, the same number was equally virulent at a later period, when the total number of organisms had apparently undergone a great decrease and none remained but the smaller "diplococcoid" bodies, which for the most part were intracellular. This series of observations, which has been repeated many times leaves the impression that the cells with the large amount of interpolar substance are involution forms, whereas the shorter "diplococcoid" bodies and the solid staining cells represent the more active proliferating organism.

Examination of the alimentary sac, salivary glands and oviduct, disclosed the presence of large numbers of similar organisms, but here the "proliferating" forms are much more numerous than the so-called involution forms. These organs, in a certain sense, represent free surfaces and render possible the removal of the products of bacterial metabolism and a renewal of food substances for the mocroorganisms. The eggs, on the other hand, are closed sacs, covered with a mucilaginous substance, which renders impossible the separation of deleterious and inhibiting material; when the bacterial proliferation has reached a certain degree further growth may also be limited because of exhaustion of the food supply by the growing embryo. Thus it is conceived that only the younger and more resistent bacilli survive, and appear in the embryonic cells and later in various tissues of the active tick.

That a specific agglutination reaction can be obtained with the organisms as they exist in the eggs has been reported previously.[10] From fifty to one hundred eggs, depending on the number of organisms they contain, are crushed in about 1/20 c.c of salt solution, and the suspension shaken until the distribution of the bacilli is uniform. On account of the small quantity of material available it is necessary to use the hanging-drop method, and since the emulsion is so dense in refractile elements from the eggs, determination of the result cannot be made with the moist preparation. After two hours' residence in the thermostat, the cover glasses are removed, the drops permitted to dry, after which they are fixed in absolute alcohol and stained with the solution of Giemsa. I may quote the results from the article mentioned above:

"The serum of the normal guinea-pig either causes no agglutination at all, or at the most produces only slight agglutination in proportions of 1 to 1 and 1 to 20. Dilutions higher than this cause no agglutination. In testing the agglutinating powers of immune serums, three animals which had been infected from different sources, and had recovered, were used. One (1751) had been infected with a dermacentor from Idaho; another (1692) with a strain handed down direct from guinea-pig to guinea-pig for nearly three years without the intervention of ticks, the original infection having been obtained from the blood of man; the third (1757) with a strain kept in the same way since last spring. Graded dilutions, beginning with 1 to 1 and going as high as 1 to 400, were used in the different series, with the striking result that a complete agglutinating power was present in the three immune serums in dilutions up to 1 to 320. It was somewhat less in a dilution of 1 to 400. The highest dilution which will cause clumping has not been ascertained.

"No fresh immue serum from man is at hand, but tests were made with three specimens which are about five, seven and nine months old, respectively. They have been preserved in the ice chest with the addition of 0.3 per cent. of chloroform. The peculiar phenomenon of failure to agglutinate in concentrated solution was noted with all three.* With the oldest serum no agglutination occurred until the dilutions of 1 to 320 and 1 to 400 were reached, when incomplete clumping was produced. With the second there was no agglutination in the dilution of 1 to 1, distinct clumping in 1 to 20, 1 to 40 and 1 to 80, with little or none in higher dilutions. In the serum of five months' standing the reaction was absent in the dilutions of 1 to 1, 1 to 20, and 1 to 40, positive but not complete in 1 to 80, 1 to 160, and 1 to 240, with very little clumping in 1 to 320, and 1 to 400. Normal human serum caused clumping in a dilution of 1 to 1, a very slight amount in 1 to 20, and none at all in the higher dilutions."

*The "agglutinoid" phenomenon.

These experiments have now been repeated many times with invarying results, in one instance distinct agglutination being obtained with the immune serum in a dilution of 1 in 1000.

The result of the agglutination test, then, is a distinct one. The blood of the immune animal contains agglutinins in high concentration for the bacillus, whereas these bodies are almost entirely absent from the serum of the normal animal. Hence, in the light of experience we must either conclude that the organism is present in the body of the animal during his attack, or suffer our faith in the value of the agglutination test for diagnostic purposes to be shaken.

Having outlined the observations which favor the position of the bacillus in question, I may refer to other findings, which apparently throw some discredit on it.

Scientific proof, among other things, would seem to demand that the bacillus be found constantly in all virulent ticks and eggs, and that it be absent constantly from all non-virulent material. In the early stage of this study eggs from ticks which had been definitely proved to be non-virulent were not at hand, but in view of the presence of the organism in the internal organs of the virulent tick, it was considered that the tissues of non-virulent ticks would serve as satisfactory controls in the place of normal eggs. It so happened that in the material then available for study no bacilli could be discovered in the salivary glands, genital organs and alimentary sac of normal ticks, and the results were considered as satisfactory and confirmatory.

Later, when more material was available, and particularly when the eggs from non-virulent ticks were obtained, it was, to say the least, a cause for astonishment, that bacilli of exactly similar morphology were found, often in great abundance, in both eggs and tissues which experiments showed to be absolutely without virulence. Continued observations, indeed, showed that an organism of this character is present with almost perfect constancy in the eggs and tissues of *Dermacentor venustus* and *D. modestus*, regardless of their infectivity. In only occasional individuals has it been impossible to find them.

Not only do they resemble exactly the bacilli found in virulent eggs and tissues in their morphology, but they respond to the specific agglutination test in the same manner, *i. e.* they are agglutinated by immune spotted fever serums in high dilutions and not by normal serums, except in dilution of 1-10, or 1-20. Therefore on the basis of morphology and the agglutination test there seems to be no question but that the bacilli found in avirulent eggs are identical with those found in the virulent.*

The situation, therefore, is a perplexing one. In favor of the causative relationship of the bacillus are the following two points: First, the presence in infected blood of forms which correspond in their morphology with those seen in the eggs and tissues of the tick; and, second, the positive agglutination

*Such bacilli could not be found in the eggs and tissues of specimens of *Ornithodorus megnini*, *Amblyoma americanum*, and an eastern *Dermacentor* [variabilis (?)].

reaction with immune serums in contrast with a negative result with normal serums. Against it is the fact that organisms of similar morphology, which respond to the agglutination reaction in the same manner, are found in the tissues and eggs of the non-virulent ticks.

One may entertain one of three hypotheses, as affording an interpretation of the results. It may, in the first place, be assumed that the organism described is merely a constant associate of the true virus in the infected animal, and consequently, although not having a necessary relationship to the disease, it may cause the formation of agglutinating substances. An example of this condition apparently exists in hog cholera, in which the true virus is very minute and filterable, whereas the hog cholera bacillus is only a more or less constant associate in the general infection. Against such an assumption in this case, however, are the facts that the virus of spotted fever is not filterable, and in the perfectly fresh eggs, in which there is the least possible morphological confusion, the bacillus described is the only organism which can be recognized. Or, second, one may suppose that for some unknown reason the agglutination reaction is not specific in this case, and that the clumping of the bacilli by the immune serum, in contrast to the negative action of normal serum, is brought about by some peculiar and unusual conditions in the experiments as they were performed. The possibility however, does not seem sufficiently strong to shake our faith in the time-honored specificity of the agglutination reaction. Or, finally, it may be assumed that the bacillus in question is the true cause of spotted fever, and that it has a tendency to undergo a loss of virulence as a consequence of long residence in the tissues of the tick, thus explaining the non-infectivity of the eggs and tissues of "normal" ticks which are rich in similar microorganisms. Such an assumption carries with it the idea that the virus of spotted fever in an attenuated form has an exceedingly wide distribution in the ticks of the Rocky Mountain States, and that it assumes virulence only under certain conditions, such as might be attained by sufficiently frequent passage through some suitable animal. If a virulent tick and its progeny do not, within a certain period, feed on a susceptible animal and convey spotted fever to the latter, it is possible that the strain of microorganisms which they contain becomes hopelessly avirulent and incapable of producing infection in any animal save the tick itself. If, on the other hand, they do convey the disease to susceptible animals before the strain has lost its virulence, the organisms may again be acquired by other ticks, and the period of pathogenicity thus prolonged. Indeed, scarcely any fact is better known among bacteriologists than the loss of virulence which a microorganism may undergo for one species of animal as a consequence of repeated passage (long residence) in another species, and the frequency with which various pathogenic organisms lose virulence for a host in the absence of occasional passage through the host, is known to all. Further, I may call your attention to evidence already cited that strains of the spotted-fever virus showing differences in virulence actually do exist in nature, as illustrated by the low virulence of the Idaho strains for both man and the guinea-pig in contrast with the high virulence of the virus of Montana. Reasonably, therefore, strains of still less or no virulence for these animals may exist under natural conditions.

As a working basis, then, I have chosen the last assumption as being the most reasonable and in best accord with the known facts. On the one hand it is hoped that the bacillus may yet be cultivated, in spite of many failures up to the present time, after which, proof of its position may be more easily obtained. At the same time another type of experiments is being carried on, which, there is reason to believe, will be equally decisive as to the relationship of the bacillus. The possibility of vaccination against spotted fever has already been determined, and the method of sero-vaccination has been described.[11] Successful vaccination, not hitherto reported, has been accomplished by the injection of the tissues and eggs of virulent ticks (rich in bacilli) after the material has been sterilized either by desiccation or by chloroform. If the microorganism under discussion is the cause of spotted fever, and if the bacilli found in a virulent material are merely attenuated strains of the virulent organism, equal success may be attained in vaccination with the latter. Although this has, indeed, been accomplished quite recently, it seems desirable to await the study of a more abundant material before submitting further conclusions.

Prevention and Serum Therapy.—To go into detail regarding methods of prophylaxis and control of spotted fever, which have been evolved on the basis of the results cited, would be to trespass too greatly on your time. An account of the procedures recommended is published in a Report to the State Board of Health of Montana, previously referred to.

Serum therapy, as practised with an immune serum derived from the horse, has not afforded decisive results, and perhaps for several theoretical reasons. In the first place, a degree of immunity in the horse greater than that established by simple recovery from the infection cannot be obtained until the organism can be cultivated and injected in excessive quantities. The repeated injection of virulent blood into an immune animal is of little or no value in increasing the quantity of protective antibodies because of the comparatively small quantity of virus which such blood contains. The immune serum is of such strength that from 0.3 to 0.5 c.c. protects against 1.0 c.c. of virus (approximately 1000 pathogenic doses). Second, experiments with animals have shown that the serum cannot be expected to exert a marked curative effect when it is given later than the second or third day after inoculation, and even in this case such an amount is required as to reach an almost prohibitive quantity when translated into terms of the human body weight. Further, it is very exceptional to obtain cases of spotted fever earlier than the third to the fifth day of sickness, *i. e.* until the eruption renders the diagnosis reasonably certain. Third, it is probable, though not a demonstrated fact, that the serum is bactericidal rather than antitoxic in its nature. If this proves to be correct, experience with other similar serums augurs a low curative value regardless of the concentration of germicidal antibodies.

No unfavorable effects, so far as can be determined, have attended its use. The advisability of modifying the technique of administration so that large quantities are given *intravenously* early in the course of infection is still a subject for consideration.

CREOSOTE TREATMENT OF PULMONARY TUBERCULOSIS.*

By BEVERLEY ROBINSON, M.D.,

NEW YORK

First of all, I ask pardon of the Society for again taking up even a few moments of their time with this well-worn theme. I would not do it unless I thoroughly believed in its very great importance and unless, at the same time, I felt I might correct a few errors of thought and practice.

To begin with, I wish to affirm that so far as I know, I practically introduced the use of creosote treatment among practitioners in New York and elsewhere in the United States, by a paper read before the Association of American Physicians (Transactions of the Association, Vol. III, p. 305) over twenty years ago. In that paper I made statements based upon numerous recorded and painstaking observations, which were true then, and are true now. Since that date, I have written and spoken many times upon this subject, and tried in every way, to convince my colleagues that I was in dead earnest in regard to the doctrine preached. To-day I am thoroughly convinced that we have absolutely no medical treatment of pulmonary tuberculosis at all equal to the creosote treatment properly used and insisted upon. In fact, I might say without much fear of effective contradiction, that no other medical treatment up to date has any great value at all, except so far as temporary relief, perhaps, of symptoms is concerned.

What I should like very much at this, or better still, some future meeting of the Society, would be a full and frank discussion of the facts I have presented to the profession already on many occasions, and that their great value should be sustained and corroborated, or else, through that discussion, their negation should be finally affirmed and supported.

It is idle and wrong to my mind, to be building sanatoria and spending large amounts of money to accomplish very little that is really useful and enduring to even a few sufferers, when we consider the vast number of the afflicted who can never hope to be treated in this way, and the fact that they, the vast majority, must finally be taken care of, as well as may be, in their own homes. It is well nigh criminal to ignore these, and other facts that may become patent and well known to all.

I would not repeat myself at length at this time, since by reading my communications in *American Medicine*, March, 1909, in the *New York Medical Times*, of October, 1908, not to speak of an article in the *American Journal of the Medical Sciences*, for August, 1908, anyone desirous of knowing accurately what I believe and reaffirm now, may become fully informed.

Finally I state that by the combined, persistent, intelligent use of beechwood creosote *internally* and by *inhalation*, many patients may be saved who otherwise would die. In nearly all cases, no matter what the stage of the disease, much relief to symptoms may be obtained. This treatment is very simple and inexpensive, and interferes with no other rational doing. It greatly supplements that doing.

Creosote treatment is of great value as a *preventive treatment*, when pulmonary tuberculosis is a menace to the individual, either by reason of constitutional tendency, exposure to infection, or both. To judicious rest, when required, fresh air, and proper food, add creosote treatment, with or without lime salts, and there is at present little or nothing in the way of further treatment to insist upon.

I have added to my treatment of pulmonary tuberculosis on several occasions during the past few years the use of the lactophosphate of lime. Is this addition as valuable as the use of insoluble carbonate and phosphate of lime vaunted by P. Ferrier? I am not yet prepared positively to state; but at least on theoretical grounds I believe it is. Is Ferrier's dietary, excluding fats and all acids, and indeed all foods that make acids in the economy, really better than what we all are and have been insisting upon in our practice, public or private? I do not as yet know. What I do know is that Ferrier's statements, corroborated by Letulle, of Paris, are startling, to say the least, and if true, are a sad indictment of human fallibility.*

A PLEA FOR A REFORM IN MEDICAL EDUCATION.

By EDMOND SOUCHON, M.D.,

NEW ORLEANS, LA.

PROFESSOR EMERITUS OF ANATOMY, TULANE UNIVERSITY.

It must be evident to other educators and practitioners of medicine that the constant increase of the requirements and examinations of the program of medical education in the colleges of the United States, and in fact all over the world, is harassing students and is truly beyond the brain capacity of a good many of them, thereby impairing their receptivity for desirable and indispensable knowledge. This certainly calls for a halt and for deep consideration and a reform of some sort to check, reduce, and regulate this burden on the students.

Having been an educator all my life, I am certainly in favor of the acquirement of as much knowledge as possible, but surely not to the detriment of final results.

To cover the programs or curriculums, *essentials are neglected at the expense of nonessentials*, and the result is that medical colleges fail in accomplishing their supreme duty, which is primarily to train students properly for the work that awaits them

*After this article was in type I received a letter from Dr. Antonio Stella of this city, in which he writes: "In reply to your inquiry as to the results I am having with the creosote inhalations, I am glad to say that I have found them very useful in many cases of bronchopneumonia and bronchitis, either simple or associated with pulmonary tuberculosis. I have an opportunity of advising such inhalations very often in my practice and at the clinic, and I have no doubt they are doing good work."

upon leaving the college, that is, that of general practitioners of medicine competent and able to diagnose and treat successfully the patients who will call upon them.

The objection, to my mind, is not so much the amount of matter in the programs as the details and minutiæ the students are called upon to attend to and to remember, and which they cannot simply because the majority of them have not the aptitude for these minutiæ, and no ambition to know them. These confuse them and prevent them from mastering and remembering the essential facts which all fairly educated practitioners should be thoroughly familiar with.

In about all the laboratories and special clinics a great deal of time is occupied in compelling students to study and to do detail work in which the larger number is not interested, as they instinctively feel that it will be of little service to them in the practice of medicine.

For instance, in the laboratories of histology and of pathology, much valuable time is given to making students stain and mount sections, for which work many have no aptitude. Much of that time should be devoted instead to making them study and to quizzing them on typical slides made by expert technicians. I know distinguished surgeons and physicians who have never made a section or a culture or mounted a slide, who are nevertheless thoroughly familiar with histology and pathology from the study of slides made by others.

In the laboratory of physiology most of the experimental work should be done to sections small enough to enable all of them to see the details of the experiment.

The teaching of specialties to students should be limited to the study of the common diseases which practitioners are likely to meet pretty often. Great stress should be made to impress on the students the symptoms indicating danger that they may recognize them in time to send them to specialists before incurable damage has been done through ignorance and oversight.

It is the detail work that should be reduced and the time thus saved devoted to essentials and those facts which the students will butt against as soon as they go out into practice, *i. e.* especially diagnosis (clinical and laboratory), prognosis, and treatment. Too much time cannot be given to the laboratory of clinical medicine.

Thus reduced to the needs of the practitioner of medicine, the understanding of the contents of the program should be insisted upon for graduation.

All the text-books of all the branches should be cut down two-thirds at least, but a fair knowledge of their contents should be required for graduation. A text-book on anatomy, for instance, should not exceed some 350 octavo pages, all needed plates included. The print should be no finer than that of the *Journal of the American Medical Association*. It is ludicrous and pitiful to see a beginner trying to work out his dissections with the ponderous books they use, which books are, most of them, splendid books of reference or cyclopedias but not fit for students in the dissecting room.

Lectures on general laws and principles of the various branches should be delivered to students, but the practical details, the facts, should be eliminated from such lectures and imparted in the laboratories, at the bedside, and in the dead house. These lectures should include remarks on the peculiarities of the most important points on each subject (anatomy, physiology, medicine, surgery, etc.), it being assumed by the teacher that the facts are known to the hearers and only the special features to be dwelt upon.

Alongside of their brief text-books, the equipment of students should comprise cyclopedias on each branch of medicine, which would give them all the details and minutiæ they may desire on any subject or point.

Written examinations should be reduced to a minimum and graduation based upon attendance, attention, quiz marks, and knowledge, and the estimate each teacher places on the mental value and ability of the candidate.

Over and above the course to make efficient general practitioners or Doctors of Medicine, there should be special courses open to those who wish to become proficient in special branches, and a special title and diploma should be awarded to those who have successfully passed examinations on one or more of those special branches (chemistry, anatomy, surgery, ophthalmology, gynecology, etc.).

It is truly saddening to see young graduates start out as specialists who have but a smattering and no experience in the branch which they claim to treat.

The matter that should compose the programs and the text-books should be decided upon by a board composed of members of the Association of American Colleges, of the Council of Education of the American Medical Association, and also of some general practitioners of medicine.

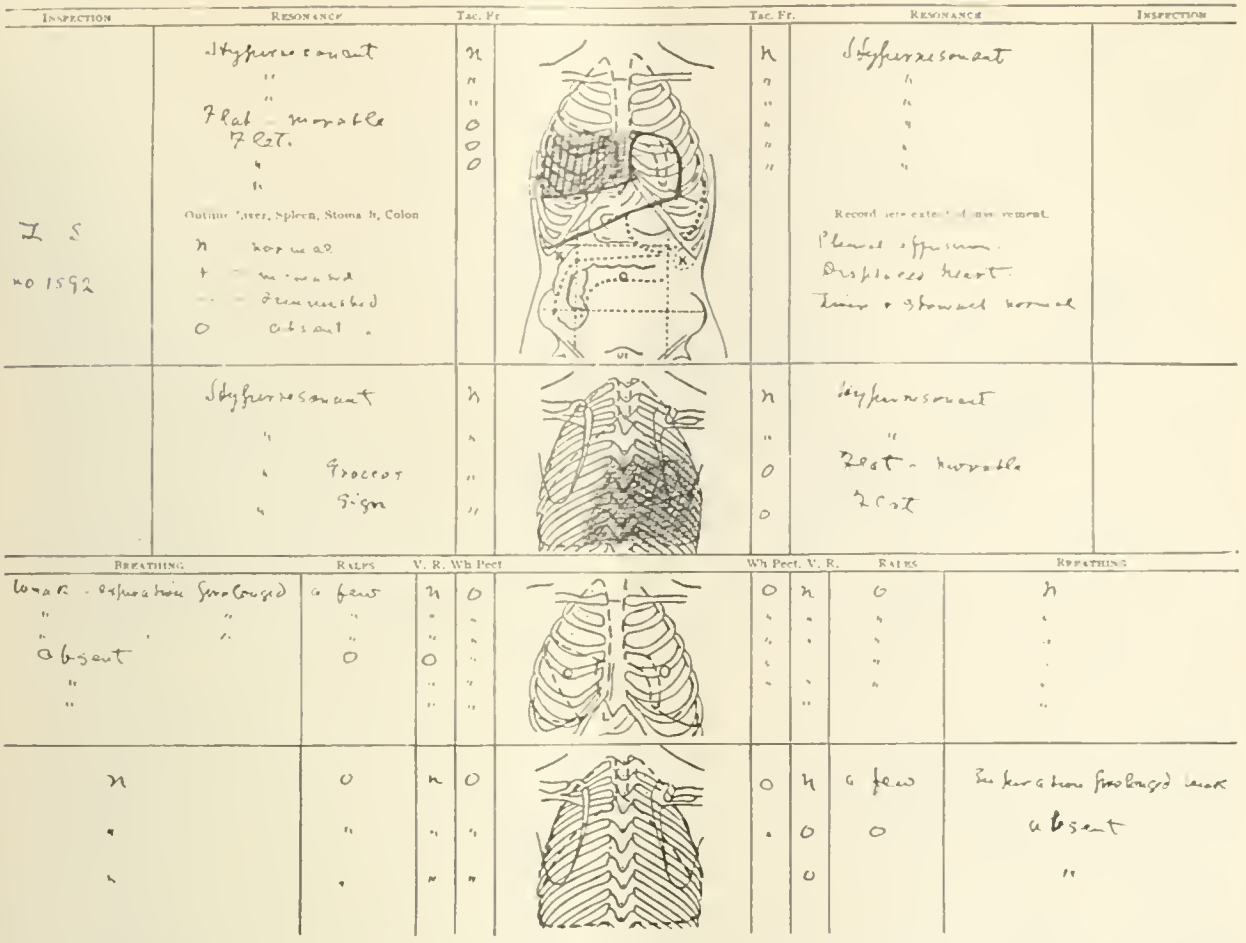
A CASE OF IDIOPATHIC HYDROPNEUMOTHORAX WITH COMPLETE RECOVERY.

By A. P. FRANCINE, A.M., M.D.,
PHILADELPHIA, PA.
PHYSICIAN-IN-CHIEF STATE DISPENSARY FOR TUBERCULOSIS.
AND
H. R. M. LANDIS, M.D.,
PHILADELPHIA, PA.
PHYSICIAN-IN-CHIEF TUBERCULOSIS DISPENSARY JEFFERSON MEDICAL COLLEGE HOSPITAL.

L. S. Jefferson Medical College Hospital, No. A-11189, white adult male, was admitted to the medical service of Dr. H. A. Hare on February 23, 1909, with the following history: "Suddenly Sunday morning he was seized while eating his dinner with severe pain in right anterior chest. The pain resembled the stab of a knife. He immediately became weak, faint, pallid, and had to be carried back to bed. He suffered with air hunger, and says that if he could have walked he would have run to the window for air as he could not get his breath. He states that three or four days prior to Sunday he had felt weak and had a slight cough, but did not pay especial attention to his condition, as he was accustomed to attacks of colds."

From this it will be seen that the history of onset was typical of pneumothorax. The patient's family history was without significance except for the absence of any history of tuberculosis. His previous personal and medical history was also without significance, having had no infections except in childhood, and there being no history of contact with tuberculosis. He said that he had lost some weight.

Without going into the details of the complete physical examination, examination of the thorax showed markedly decreased expansion on right with prominence, and increased motion on left. The apex beat was visibly displaced to the right. The patient showed all the typical signs of hydropneumothorax. The coin test was clear and distinct, "ex-



quisite," as it is marked on the chart, while the succussion splash was plainly demonstrable and heard by the patient himself. He was repeatedly demonstrated to the ward classes in medicine by both Dr. Hare and Dr. Landis, on account of the distinctness of the physical signs of hydropneumothorax.

Second skiagram of L. S. taken by Dr. Leonard, May 4, 1909, shows lungs normal, with enlargement of peribronchial glands more marked on right. The heart normal in size and position in systole. The white spot in the stomach is gas.

During his entire stay in the Jefferson Hospital he was unable to lie down wtihout becoming extremely dyspneic and cyanotic. It was a matter of comment during his stay in the hospital that the left lung was apparently normal. The percussion note over the right apex gave a skodaic resonance both back and front, with other signs of relaxed lung. Below, over the area of pneumothorax, vocal fremitus, tactile fremitus, and breath sounds were absent. The note was tympanitic and there was an area, over the effusion, of movable flatness.

In view of the existing condition, the secondary anemia, the loss of weight, and a positive cutaneous tuberculin test, the diagnosis of pulmonary tuberculosis complicated by hydropneumothorax was made.

L. S. presented himself at the Penna. State Dispensary for Tuberculosis (No. 21) on April 7, 1909, case No. 1592, in the service of Dr. William G. Turnbull. He gave a history of having been in the Jefferson Medical College Hospital under the care of Drs. H. A. Hare and H. R. M. Landis, and said that he had been frequently demonstrated to the students in ward class. He consequently knew a good deal about his previous condition and said that he had had a hydropneumothorax with a succusion splash, which he could plainly hear and feel himself. Dr. Turnbull made a careful examination and found no evidence of pneumothorax whatever, but an extensive plural effusion reaching to the third rib on the right side. He made the following note: "Patient has typical history of hydropneumothorax, said he had succussion splash, could hear it himself until recently. No signs of pneumothorax can be elicited now. Signs of large rightsided pleural effusion."

Dr. Francine examined the patient and confirmed Dr. Turnbull's view in every detail, and the case was referred to Dr. C. L. Leonard for skiagram. The first plate was taken April 10, 1909, and showed a large pleural effusion. The patient's temperature

at the first visit was 99 3-5°, respiration 22, pulse 88. He gave no history suggestive of tuberculosis with the exception of loss of weight, his highest previous weight having been 160 pounds, while his present weight was 138½ pounds. He was under treatment until May 4, 1909, during which period he paid in all five visits to the dispensary. His temperature subsequent to the first visit was uniformly normal, and his pulse never above 84 and as low as 68. His weight on the last visit was 141¼ pounds.

During the course of his treatment the pleural effusion rapidly diminished, and upon final reexamination at the last visit there was no evidence of any fluid in the chest whatever, but what was more remarkable, there was no evidence of any pleuritic thickening nor of any localized tuberculous process in his lungs.

His hydropneumothorax had come and gone and left no trace of its existence. Tactile fremitus was normal all over chest, expansion normal and symmetrical, and the breath sounds normal except in so far as the breathing was somewhat emphysematous over both lungs. The percussion note over the entire pulmonary area was slightly hyperresonant. Dr. Turnbull's note reads: "Signs of effusion have disappeared. Tactile fremitus normal." He was referred to Dr. Leonard for a second plate, and this skiagram showed the chest to be free from any fluid and the lungs clear throughout and without evidence of tuberculosis localization except in enlarged peribronchial glands.

The above history and course of this case make it of considerable clinical interest. The vast majority of cases of hydropneumothorax develop in the course of pulmonary tuberculosis and most frequently in advanced cases from the rupture of a cavity or area of softening and the condition is usually a terminal one.

While this patient was very probably tuberculous, that is, had a chronic tuberculous adenitis, there were no signs nor symptoms of pulmonary involvement. He showed evidence, however, of some emphysema and it would seem likely that there had been a rupture of an air vesicle, permitting the entrance into the pleural sac of a small quantity of air. This was sufficient to induce effusion and give rise to a true hydropneumothorax. The fluid increased to large proportions and the air was compressed and absorbed and the picture changed to one of simple serous pleural effusion. The air having disappeared, the cause of the pleural effusion was gone and the fluid was rapidly absorbed.

The accompanying chart and skiagram explain themselves.

A FRAGMENTED FILIFORM REMOVED FROM THE MALE URETHRA WITHOUT OPEN OPERATION.

By VICTOR COX PEDERSEN, A.M., M.D.,

NEW YORK.

GENITOURINARY SURGEON TO THE OUTPATIENT DEPARTMENT OF THE NEW YORK HOSPITAL AND HOUSE OF RELIEF (HUDSON STREET HOSPITAL).

THE problem of passing a tight stricture with a filiform guide is partly solved by the selection of the type of filiform used. The composition (rubber) instruments are extremely unsafe and should be discarded by all operators. The woven filiforms are not infrequently so flexible that they coil within the urethra in front of the stricture and may deceive the operator with the impression that he has passed onward into the bladder. Probably whalebone guides are the instruments of choice for this service and are procurable in various sizes from almost horse-hair thickness to 1 or 2 millimeters in diameter. Relatively, all these whalebone guides possess sufficient spring and rigidity to permit them to pass through the vast majority of strictures. One fact about whalebone is, however, not as well understood as it should be, namely, that through either disease or changes incident to frequent sterilization and long use, whalebone becomes brittle, so that it will fragment partially or completely both transversely and longitudinally. For this reason no whalebone guide should be used before it is examined as to splits, cracks, exfoliation, and other changes. Of course, it is also necessary in buying whalebone guides to examine them, not only as to these points, but also as to whether or not rubber imitation is being substituted.

Upon the point of disease of whalebone guides, instrument dealers state that it is advisable to store all whalebone instruments in air-tight glass tubes to keep them from the insect which attacks this material.

The writer desires to report the following case in which a whalebone guide broke within the urethra and was removed without open operation.

G. C., white, 52 years old, married, born in the United States, always has enjoyed very good general health, usually following the vocation of licensed engineer, necessitating hard work. He admitted a number of infections with gonorrhea extending backward many years into his youth. Symptoms of stricture developed during the past five or six years with total obstruction on the day of his first call, May 31, 1903.

Physical examination showed a well nourished, heavy, intelligent individual, not alcoholic, symptoms of cystitis, hypertrophy of the prostate, and obstructing stricture. Operation for the stricture and the prostate refused, only dilatation of the stricture accepted.

Treatment. Filiform passed with difficulty and allowed to remain in 24 hours when dilatation with tunneled and grooved sounds was begun and carried up to 16 Fr. during the next few weeks. He then disappeared and returned with a relapse in July, 1904, which was treated in the same manner successfully. Warning was given to continue the treatment at this occasion until larger caliber was reached and maintained against relapse by regular visits. Hope was held out that if this were accomplished the prostatic symptoms might somewhat improve. Notwithstanding this warning he again withdrew from treatment until December 11, 1907. In this relapse still greater difficulty was encountered in passing the stricture. He was, however, dilated slowly from 6 Fr. up to 17 Fr. After a lapse from treatment he returned with total obstruction, due partly to the stricture and partly to the prostate. A filiform was rather readily passed and a sound threaded over it, which unexpectedly broke the filiform near the bulb of the urethra. This was discovered only upon removing the sound with the outer part of the filiform in the tunnel. It was assumed that the other half was either in the deep urethra or in the bladder itself. Before deciding upon an open operation, however, the author hit upon the following successful and simple procedure: A urethroscope was passed into the urethra down to the face of the stricture where coiled upon itself was seen a long thread-like fragment of

the whalebone guide. An ordinary woman's knitting-needle was passed down to this loop, seized it and straightened it out within the urethroscope and brought its tip so close to the eye-piece of the endoscope that it could be seized with a Kelly "mosquito" artery clamp. After this it was easy enough to withdraw clamp, urethroscope, and filiform.

F. J. Lydston[1] states that the filiform may be carried into the urethra along with the sound being brought again to light when the sound is withdrawn. This, in the opinion of the writer, is a very improper and hazardous procedure. In no circumstances should the filiform ever leave the eye or the hand of the operator. For this reason it is well to have the filiforms two feet long, part of which is coiled within the bladder and the remainder lies within and without the urethra, thus permitting testing of the freedom with which the sound slides over the filiform without ever disengaging the filiform from the cavity of the stricture or bladder. For further details as to the proper manner of passing a sound over a filiform, the reader is referred to an article of the writer[2] in the *Annals of Surgery* for 1909.

Before ever threading a sound over a filiform guide, careful palpation of the urethra should be made in order to ascertain whether or not the filiform has doubled upon itself and is beginning to turn forward toward the meatus as shown in Fig. 1. The diagnosis of this accident is always made by eliciting from the patient whether he has had the subjective sensation of the filiform sliding through the stricture and again through the sphincter of the bladder and finally of coiling within the bladder. This accident of doubling upon itself and passing forward toward the meatus is far more common than one would suppose and almost invariably the patient is able to state that all the sensation he has had is in the front part of the urethra. Objectively, this accident may be diagnosticated by making out with the finger two strands of filiform where only one should be present, or if there is doubt in palpation an urethroscopy will settle the

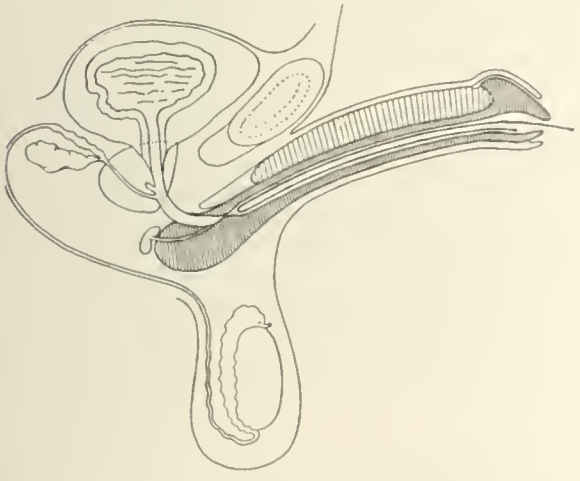


Fig. 1.—The anatomical details of this diagram are sufficiently clear and require no notation. The stricture is plainly shown just in front of the bulb. The filiform also is clearly represented doubled upon itself at the face of the stricture with the shorter element almost presenting at the meatus.

matter. It is obvious, of course, that a sound carried along a filiform so doubled will almost invariably cut through the same at the base of the loop.

Another accident which may happen to a filiform as the sound passes down it is shown in Fig. 2. This doubling twice upon itself is usually due to the fact that the operator has not held the free end of the filiform sufficiently stationary, thus the sound carries the filiform against resistance from within the bladder, making a double loop of the filiform upon itself above or on each side of the sound. The diagnosis of this condition is much more difficult than that of the foregoing. Commonly the subjective sensation of the patient is of no value whatever. The endoscopic tube cannot be used, of course, because the sound is in the urethra. Careful palpation commonly around the point of the sound will reveal three strands instead of one strand of filiform guide: one being the straight filiform as it lies in the groove of the sound and the other two being the reduplications as they lie beside or above the point. Slight rotation of the point always aids in distinguishing the one from the other. If doubt exists, only one thing remains to be done, namely, to release the free end of the filiform outside the meatus and slowly withdraw the sound. This will commonly bring to light the filiform doubled twice upon itself at the meatus exactly as it lay at the face of the stricture.

Fig. 2.—As in figure 1, the anatomical details of this diagram are sufficiently clear to need no notation. The stricture is plainly shown in front of the bulb. The filiform also is clearly diagramed doubled twice upon itself at the face of the stricture and above the sound. The straight strand of the filiform also appears leading from the urethra and again through the stricture into the bladder where the redundancy is coiled within that viscus, thus demonstrating the advantage of using filiforms two feet long.

Ichthyosis and the Thyroid Body.—E. Weill and G. Mouriquand believe in the origin of some cases of ichthyosis in a failure of the thyroid gland to act. Two cases treated by him, the histories of which are given by them, are examples of this condition. In some cases ichthyosis coincides with an absence of the thyroid gland or profound lesions of it. In others the symptoms are those of thyroid lesions, and are associated with myxedema, both in congenital and acquired ichthyosis. In others there is no manifest lesion of the thyroid, and yet the ichthyosis is cured by thyroid extract. Some cases attributed to hereditary syphilis show thyroid lesions. Since the gland presides over the nutrition of the cellular tissue beneath the skin and the derma, it is logical to admit that it acts on the evolution of the superficial cutaneous tissues.—*La Presse Médicale.*

TABLE 1.—A table showing by month the number of cases of typhoid fever occurring in Philadelphia from January, 1898, to June, 1909, inclusive.

PRELIMINARY REPORT OF A STATISTICAL ANALYSIS OF OVER SIXTY-EIGHT THOUSAND CASES OF TYPHOID FEVER.

By ABDULLAH K. SALLOM, M.D.,

PHILADELPHIA, PA.

THIS report represents a study of the cases of typhoid fever which have occurred in Philadelphia during a period of eleven and a half years. The figures which form the basis of this report have been obtained from the official weekly report of the Bureau of Health, so that they may be considered quite reliable.

From January, 1898, to June, 1909, there occurred sixty-eight thousand nine hundred and forty-three (68,943) cases. Of this number eight thousand one hundred and two (8,102) died, giving a mortality of slightly over 11.75 per cent. A study of so large a number of cases is therefore not without interest.

Table 1 gives the number of cases and mortality by months, and at the foot of each column the total number of cases and deaths for each year is given. To the right of the table is given the total and average number of cases and deaths for each month. A glance at the figures will show that the greatest number of cases occurred in February, there being an average of seven hundred and fifty-nine (759) cases. January is a close second, averaging six hundred and ninety-four (694) cases. The average number of cases for each month then gradually falls, reaching its lowest ebb during July. It again rapidly rises, reaching a second maximum during September. During October and November it falls to rise again in December. This extremely interesting condition is graphically shown in Chart 1.

It is of particular interest inasmuch as it is usually stated that the disease is more common during the late summer and autumn months than at any other time of the year.

Chart 2 is of particular interest in many ways. It graphically shows the monthly number of cases and mortality during the past eleven and a half years. Marked fluctuations are noted showing beautifully the number of cases from month to month

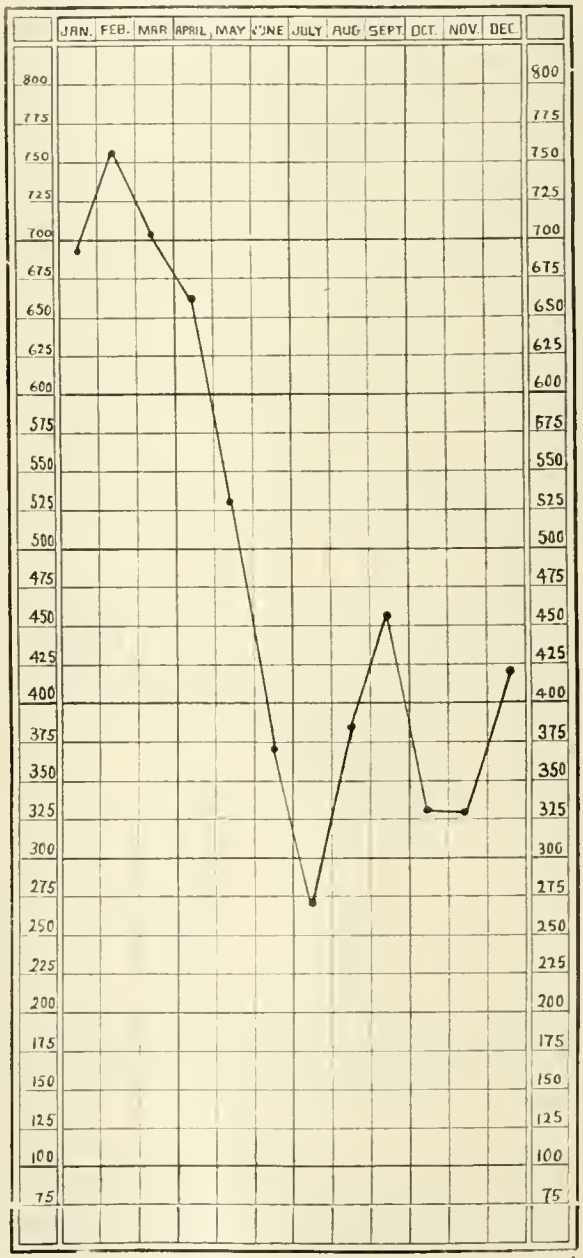

CHART 1.—Average number of cases of typhoid fever occurring during each month of the year. Statistical analysis of 68,943 cases.

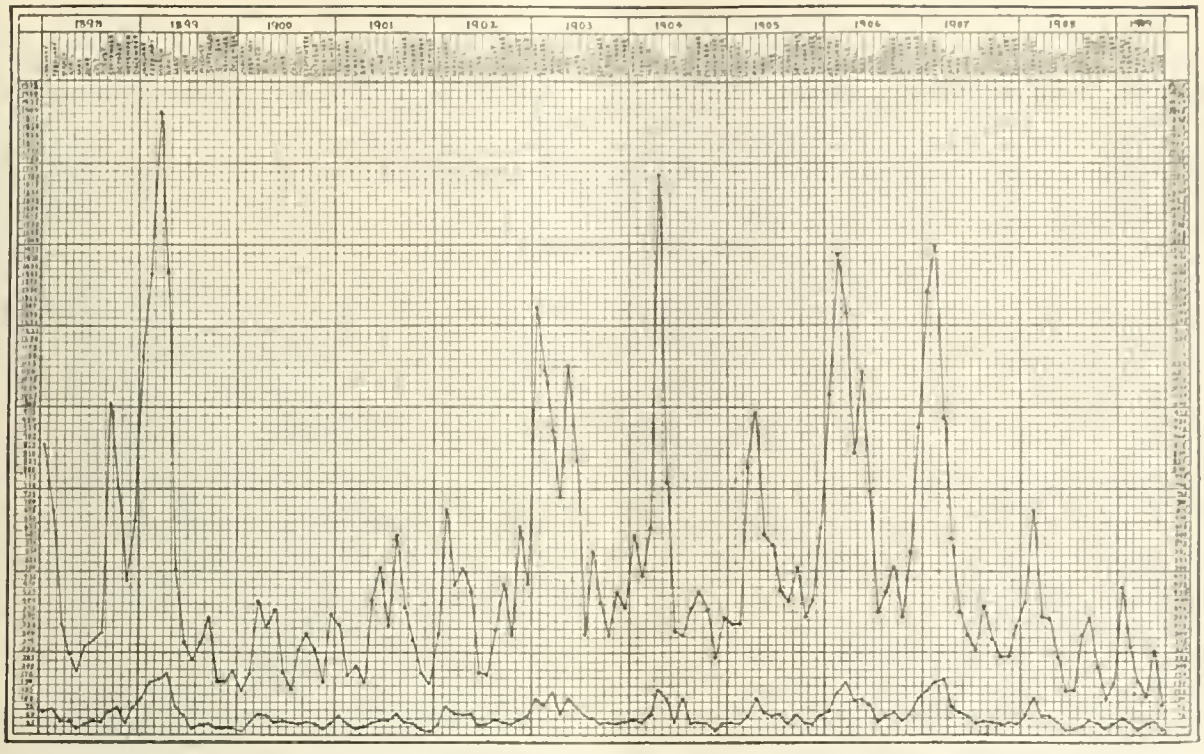

CHART 2—Showing the number of cases and mortality of typhoid fever by months; statistical analysis of 68,943 cases.

and year to year. The upper line represents the number of cases, the lower the mortality. Reading from left to right each space represents one month, and each twelve spaces are blocked representing one year.

For 1898 there was an increase of four thousand one hundred and three (4,103) cases and two hundred and thirty-eight (238) deaths over the previous year. The large number of cases for this year as well as the early part of 1899 has been attributed to the return of our soldiers. Of the total number for 1898, one thousand three hundred and forty-six (1,346) cases were soldiers who were brought to this city from the military camps throughout the country. For the next three years there was a marked diminution in the number of cases. The disease then became more prevalent, and from February, 1907, it has been gradually decreasing.

The large number of cases occurring in Philadelphia has been attributed to the polluted Schuylkill River, which is the principal drinking water supply. As early as August 12, 1902, filtered water from new filter plant was supplied to a small section of the city. Since that time the district receiving filtered water has been gradually enlarged until on February 20, 1909, the entire city was supplied with filtered water. It is of great interest and importance to determine whether the filtered water had any effect on the number of cases.

From the data which I have at hand I believe that the filtered water has been instrumental in the reduction of the number of cases of typhoid fever, for it appears that while the number of cases was greatly reduced in the district receiving filtered water, typhoid fever was still quite prevalent in the district not receiving filtered water, and in this manner increasing the general number for the entire city. On this subject I shall write in detail in the definite report.

1312 PASSYUNK AVENUE.

ACUTE GANGRENOUS CHOLECYSTITIS; GALLSTONE IN THE CYSTIC DUCT; PERFORATION OF THE GALL-BLADDER.

BY ESPY WILLIAMS, M.D.,

PATTERSON, LA.

SURGEON TO ST. MARY'S HOSPITAL.

THE report of one or a few instances of disease conditions, unless to a certain degree unusual, is hardly permissible now; overburdening, as such records do, a literature already well filled. That the instance cited here deserves some distinction from the viewpoint of its rarity in addition to the virulence of the lesion will be admitted from the following notes:

In a review of 1500 operations on the gall-bladder and bile ducts made by Wm. J. Mayo before the meeting of the American Surgical Association in 1906, there were no cases of gangrenous cholecystitis. Joseph Ransohoff reports one case occurring in his practice (*Journal of the American Medical Association*, Vol. 47, p. 395). Mayo-Robson states that the condition is one which is "seldom seen." ("Diseases of the Gall-Bladder and Bile Passages," 3d edition, page 95.) and that he has "operated upon one case in the interval between the publication of the second and third editions" of his work, a period of three years. Similar, is Moynihan's statement ("Gallstones and Their Surgical Treatment"). The findings of these latter three gentlemen, Ransohoff, Mayo-Robson, and Moynihan, are of more value than those of Mayo; their practice being found in large centers with a consequent large field for emergencies, that of Mayo being in a small town, and the majority of their cases, immense in number as they are, being "walking." In von Bergmann and Bull's "System of Surgery," gangrene of the gall-bladder is given no space; and lastly in Keen's "Surgery," perhaps one of the most valuable of all the references, the lesion is but mentioned in the chapter on the diseases of the liver and bile passages, written by the Brothers Mayo.

Case.—D. R., colored male, aged 36 years, farm laborer by occupation, was seen complaining of abdominal pain, vomiting, and fever; first by my colleague, W. D. Roussel, thereafter by us both, jointly. The family history was negative. Personally the patient had always been of a hearty disposition, having suffered from no serious illness of any sort. The present illness began three days prior to consultation with suddenly oncoming abdominal pain, accompanied with vomiting and followed by fever. Home remedies were used with the customary idea that the trouble was due to "indigestion," but without result, symptoms continuing and gradually becoming more severe. When seen the condition was as follows:

Temperature, 100° F.; pulse, 100 to 110; facies pinched and indicative of pain, dorsal decubitus, thighs flexed upon abdomen. He was vomiting constantly everything taken by mouth; and small quantities of bile and mucus with stomach empty. He complained sorely of abdominal pain. The bowels were moving very frequently, the actions being thin and yellow.

Physical examination: The tongue was coated and dry. Thoracic organs normal. The urine contained a small quantity of bile but was otherwise normal. The abdomen was slightly distended and quite rigid, especially in the right upper quadrant, and there was exquisite tenderness over the region of the gall-bladder. The pain was over the gall-bladder, extending downwards and inwards to the umbilicus and through to the back. There was no pain in the right shoulder and no jaundice. Light percussion elicited a slightly dull note over an area the size of the palm, under the right ribs. Nothing could be made out on palpation.

A diagnosis of acute cholecystitis was made. The stomach was washed out and kept empty, and an ice bag applied over the painful area. The condition of the patient remained without change during the first twelve hours after admission, except that the vomiting subsided. At the expiration of this time, however, the pain suddenly subsided—to become aggravated within the hour—vomiting recommenced and the pulse increased in rapidity; indications leading to a suspicion of rupture of the organ; thereupon operation was immediately made, as follows:

Bevan's incision was used to allow of plenty of room for working. Upon entering the cavity there was found a small quantity of thin, straw-colored fluid. The gall-bladder could not at once be seen, that area being covered by dense and greatly inflamed omental adhesions. In freeing adhesions to get at the organ a small pocket, containing about two ounces of dark fetid bile, and situated above the transverse colon, was opened. After liberating all adhesions the gall-bladder was found, deeply situated and slightly reduced in size. Its walls were deeply injected and the lower third of the organ, which had been free from adhesions, was covered by thick flocculi of fibrin. The entire fundus of the bladder was gangrenous, and near the periphery of the dead area a small opening exuded thick, black bile. The organ was emptied, through a trochar, of about one ounce of thick, black, and foul-smelling bile; the gangrenous area was pinched off with forceps and the remainder of the cavity dried out. With the finger upon the outer surface of the gall-bladder a small stone could be felt, wedged within the cystic duct, and this was pushed up without much difficulty and removed. This was the only stone present. The operation was completed by leaving several forceps attached to the half of the organ which remained, introducing a split rubber tube-gauze drain within the cavity, and surrounding the whole with a large split tube, so arranged as to protect the abdominal cavity below. The wound was closed in tier fashion. The time of operation was thirty-five minutes and patient left the table in very good condition. Ether was the anesthetic used.

Postoperative treatment: The patient was elevated in bed at an angle of 45 degrees and Murphy drip given at once. He was nourished freely as soon as possible after operation, which was not long. there being no further vomiting and but little nausea, the latter being a rather unusual feature to us, as we have as a rule been troubled quite a good deal in this way after gall-bladder work. No bile whatever was discharged from the wound for three days, after which time it began flowing freely. The forceps were removed on the third day and all other drainage on the seventh, the patient being by this time in most excellent condition. Matters then progressed uneventfully, the patient being discharged from hospital on the eighteenth day, with the wound still draining bile. Discharge of bile ceased at the end of the fourth week after operation.

The stone removed was of bilirubin-calcium, very irregular in shape, and weighed but three grains. The bile found outside the gall-bladder was evidently discharged through rupture in the gangrenous area at the time of temporary cessation of pain, the latter being due to the sudden lessening of intravisceral pressure.

In all cases of gangrene of the gall-bladder it is usual to find occlusion of the cystic duct by stone. In the case reported by Ransohoff there was no stone present, and he regarded the cause here as a possible twist of the cystic duct with occlusion of the artery of supply. Stone impaction in the cystic duct may give rise either to an hydrops of the gall-bladder or to empyema or gangrene; and it is most likely, we believe, that when the latter occurs it is due to several factors; occlusion of the artery of supply by pressure of the stone, with or without concomitant inflammatory swelling of the mucous membrane, and with or without infection of the gall-bladder itself; the ideal in this respect being the coaction of all these contributors. Gall-bladder gangrene is usually regarded as an aftermath to empyema or to phlegmonous cholecystitis; in our case there was nothing of this sort present.

In regard to technique, it would seem best to leave as much of the gall-bladder as possible. It is generally recommended that cholecystectomy be done, but the necessity for this we cannot clearly make out. Such procedure very materially increases the danger to the patient so far as the operation itself is concerned, to say nothing of the increased length of time required in its performance; and it renders drainage just so much the more difficult. In the case of Ransohoff the organ was completely gangrenous "quite to the tip," and was left, being discharged as a complete slough at the end of five weeks after operation. This is a point in technique which we believe is decidedly to be favored. In work like this is, too which has to be done with all the expedition possible, we would recommend leaving forceps attached to the gall-bladder. They provide against hemorrhage from the cut or torn mucous surface, act admirably for drainage, and do away with the necessity of fixing the tube with a suture, since the support which they give prevents possible slipping of the other drainage apparatus.

THE INFLAMMATORY NATURE OF INSULAR SCLEROSIS.

MANY of the mysteries of neuropathology are disappearing as more careful diagnostic analyses permit of a clearer correlation of symptoms with the appearances found after death. Thus, in the distinctions between hysteria and the organic conditions it was thought to resemble, precision has now replaced vagueness, thanks mainly to the efforts of Babinski. Spinal commotion has disappeared from neuropathology; and the traumatic neurosis is more and more appearing as a psychological state due to a fixed idea derived from the patient's surroundings previous and subsequent to his accident. The posterior column scleroses of tabes dorsalis itself, the supposed lesions of locomotor ataxia, are now shown to be merely the secondary degenerations of inflammatory foci situated on the radicular nerves, and due to a chronic meningitis, the result of syphilis. The formerly inexplicable cavities of syringomyelia are now known to be the result of broken down gliosis, probably residual Colnheim areas of embryonic life.

And now disseminated sclerosis, cases of which are even yet so often labeled "functional," on account of the remarkable fashion in which the several symptoms may disappear for months at a time, has had its primitive lesion detected. The discovery has been made, like the preceding examples, in Paris, this time at the laboratory of the Charcot Clinic, in the Salpétrière. Working with Raymond, professor of neurology in the University, Guiéva-Rajes, had the opportunity of examining, post mortem, a case of *sclérose en plaques* during an acute exacerbation of the disease. The patient had been ill for one year, and died of an intercurrent affection. In both cord and brain the typical chondroid islands were found; but in addition to these there were certain areas of different appearance, consistency, and contour. These were less sharply defined from the surrounding tissues; they had a reddish tinge, some of them quite bright, and they were softer. Under the microscope a definite inflammatory hyperemia was seen. There was a certain amount of diapedesis, and the tissue elements were tumefied and hyperplastic; the glia in particular had reacted, while the myelin of the nerve fibers was in many cases broken down into droplets; the axis cylinders were much less touched, only a few being moniliform. Here, then, were inflammatory zones; and, although the middle stage was not present, yet the extent and distribution of these and the relative escape of the axis cylinders were of the kind shown most conspicuously in multiple sclerosis, the older lesions of which the patient also presented.

The practical importance of this discovery lies in the orientation of future research in the direction of the infective agent which it would seem must be the basis of such inflammatory appearances. It will be necessary to detect the cases in the stage of invasion as is now being done with poliomyelitis anterior acuta by the organization of the Norwegian Health Service with such remarkable fruits. To this end, however, we must supplement the defective neurological training of the general practitioner who sees the slight febrile attacks which accompany the sclerogenic process of insular type. This may be done, either by improved technique on his part, or by the collaboration of neurological consultants when he himself fails to find the clear explanation of neurotic symptoms presented by his patients. The present fashion is most reprehensible, for it consists in labeling every unknown neurotic symptom as either hysteria or neurasthenia in accordance with the predilections of the practitioner and according to the violence of the patient's reactions. One of the chief difficulties of neuropathologists has been the defective clinical histories and examinations which accompany a case to the table; and this, unfortunately, is still the case. For there is too much of a tendency among neurologists to sit at a distance and promulgate opinions *ex cathedra*, and without due care to expound their reasons; and there has been too great a reluctance among practitioners to invoke neurological assistance in an intelligent way. Perhaps there have been faults on both sides; for if the practitioner showed a more intelligent grasp of neurological problems by informing himself of a few fundamentals of diagnosis and by reflecting upon his cases, the consultant would feel that he could safely go beyond mere opinions, and that he might venture to explain without fear of being misunderstood. Such collaboration in the case of the physician and the surgeon is of every day occurrence; and were it more general where the neurologist is concerned, there would be far fewer complaints of Christian Science, mental healing, and other irregular practices.

THE STERILIZATION OF THE CONFIRMED CRIMINAL.

THE problem of what to do with the habitual criminal, the idiot, and the sexual degenerate is one that has from the beginning of civilization puzzled sociologists, philanthropists, and penologists, and it is still being discussed. In these days the problem concerns less the existence of the indi-

vidual criminal or idiot than it does the prevention of the manufacture of new generations of potential criminals and degenerates. This might be secured, it is true, by the life-long incarceration or colonization of those unfit to procreate, yet justice or expediency forbids this in all cases. Society would have the right to demand this in its own protection were there no other prophylactic available, but such a method of treatment would not always be in the interest of the State, which should not be compelled to support the individual who might, if free, be able to take this burden off the State and even be a useful citizen were his power of future harm taken from him. Long ago castration was proposed as a means of rendering the degenerate innoxious, but the thought is repugnant, for even the criminal has certain individual rights which the State cannot take from him; it may deprive him of his life or his liberty for its own protection, but it is questionable whether it would be justified in subjecting him to the cruel indignity of castration.

Some years ago, when castration was proposed for the relief of hypertrophied prostate, and was actually performed in many cases, with apparent success in some, J. Ewing Mears of Philadelphia suggested ligature of the spermatic cord as a substitute operation which would be free from the obvious disadvantages of removal of the testes. It was in a way beating the devil round the bush, for the result is the same in the end, the operation insuring an atrophy of the testes, but the mental effect on the individual is less marked, the atrophy of the glands being gradual and nearly like that which naturally comes with age. Noting the result in such cases, it occurred to Mears that the same operation might be resorted to as a means of asexualization of habitual criminals and other degenerates and so preventing them from procreating their kind. In an article in the *Boston Medical and Surgical Journal* of October 21 he says that a bill was passed by the Pennsylvania Legislature legalizing this operation in certain cases, but failed to become a law through the veto of the governor. The advocates of the measure accepted this check, not as a defeat but as a temporary setback only in the battle in what its advocates justly regard as the cause of right and justice. "Back to the people it has again gone, with the assuring hope that the *vox populi*, more forcibly pronounced, if need be, will give to the citizens the right to protect themselves against the deadening influences of degeneracy, and, through the measures sought to be applied, give to the classes of unfortunate defectives, paradoxical as it may seem, their only true protection."

While Mears was advocating this measure of protection for society against the multiplication of its degenerate and criminal enemies, Belfield of Chicago was advocating in the same cause the operation of vasectomy, or exsection of the vas deferens. The advantages claimed for this operation are that sterilization is secured with equal certainty as by castration without depriving the individual of his sexual powers or of the benefit of the internal secretion of the glands. Vasotomy, or simple division of the vas, is inadvisable as a prophylactic measure, since it is remediable by a simple operation reuniting the divided ends of the vessels. Vasotomy or vasectomy has been indorsed by the Chicago Society of Social Hygiene, it has actually been employed with legal sanction in Indiana for more than two years and in several hundred cases, and has recently been legalized also in Oregon. The Indiana law provides that in the case of "confirmed criminals, idiots, rapists, and imbeciles," confined in any institution of the State, when, "in the judgment of the committee of experts and the board of managers, procreation is inadvisable and there is no probability of improvement of the mental condition of the inmate, it shall be lawful for the surgeons to perform such operation for the prevention of procreation as shall be decided safest and most effective." In most of these cases vasectomy, as the more simple procedure, would doubtless be preferable, but in the case of rapists, the only really effective remedy would be ligation of the cord, as recommended by Mears.

The movement is a step in the right direction and one that should receive the sanction of legislators in other States. The well-known case of the Jukes family shows what evils a sexually potent criminal may inflict through the years upon society, and if the State has the right to take life for its own protection it certainly has the right to safeguard the future by preventing what Mears characterizes as "the degrading influences of the continually flowing stream of transmitted pollution which saps the mental, moral, and physical vitality of its citizens."

THE SIGNIFICANCE OF THE NASAL SECRETIONS IN THE DIAGNOSIS OF LEPROSY.

At the Second International Conference on Leprosy, held in Bergen, Norway, August 16 to 19, 1909, a discussion was had in regard to the diagnosis of leprosy from an examination of the nasal secretions. An important communication on this subject was presented by Walter R. Brinckerhoff, Surgeon P. H. and M.-H. Service, Director of the Leprosy Investigation Station at Molokai. Together with W. L. Moore he has made an exhaustive study of this subject, the result being published in a Bulletin of the Public Health and Marine-Hospital Service. Sticker is supposed to have noted the theory that the nasal septum may be the seat of the initial lesion in leprosy, but George Pernet of London writes to the *Lancet* to say that the belief that leprosy began in the nose is of very ancient origin. In a general review of leprosy contributed by him to the *Quarterly Review*, April, 1903, he drew attention to the fact that Pliny mentioned the disease as commencing in the nose. Brinckerhoff quite rightly investigated only incipient cases. The majority of investigators have based their conclusions with respect to the above theory upon the study of relatively advanced cases. No more favorable field for such an investigation could have been selected than Hawaii. It was estimated by the investigators that six of every one thousand of the natives at large were lepers, and that therefore one

might expect to find a leper for every 165 Hawaiians examined. It was felt that from statistical data one might reasonably anticipate finding a moderate number of incipient cases of leprosy by a thorough examination of a number of Hawaiians, and that if the nose were the site of a diagnosable initial lesion, such as is seen in later stages of the disease, it should be possible to discover cases of leprosy in individuals who were unaware of the infection.

Brinckerhoff and Moore in making their examinations attempted to answer the following questions: (1) Will the systematic examination of the nasal septum and the nasal secretions reveal cases of leprosy which would pass undetected by other methods of examination? (2) When an early case of leprosy is under observation, can it be said that the case could have been detected by the examination of the nasal septum and the nasal secretions alone? The material on which the paper of Brinckerhoff and Moore was based consisted in the findings in the examination of the nasal septa and the nasal secretions of inmates of seven public institutions in Hawaii. In addition to these, patients were examined who presented themselves for treatment at the Free Dispensary and at the Marine-Hospital out-patient clinic in Honolulu. Further, every opportunity was taken to examine early cases of the disease to see if there were evidences of a primary nasal lesion on the nasal septum. Four hundred and sixty-seven Hawaiians were examined and the following conclusions were reached: (1) The routine examination of the nasal septum and the nasal secretions of individuals of a race with a high incidence of leprous infection did not reveal as many cases of leprosy as would be expected from statistical data had the method been an efficient one for establishing a diagnosis of the disease in the incipient stage. (2) The examination of the nasal septum and the nasal secretions is not of dominant value in confirming a diagnosis of leprosy in the early stages of the disease. (3) The conditions found in the noses of nonleprous children of leprous parents do not differ in important respects from those found in the descendants of nonlepers. (4) When it is not practicable to make a complete physical examination of all individuals of a class suspected of leprosy, the examination of the nasal septum and the bacteriological examination of the nasal secretions will prove of value by permitting the recognition of the most dangerous type of the disease, and is therefore worth while even if it does not reveal all cases of the disease in those who come under observation.

These conclusions are in the main in accord with the results of Thompson, Macdonald, Theroux, and Kolle. Brinckerhoff and Moore do not take issue with those who emphasize the importance of the nose as a site of leprous lesions, and who draw from that fact conclusions as to the prophylaxis of the disease. They recognize that nasal lesions in leprosy are of the utmost importance in this respect, but do not consider that the presence of a lesion on the nasal septum in an advanced case of leprosy has necessarily any significance in determining the site of the initial lesion of the disease.

Tonsillectomy for Rheumatism.

For many years the close association between disease of the tonsils and acute articular rheumatism has been a well-recognized fact. The appearance of an acute polyarthritis following close upon the heels of a follicular tonsillitis has been much too common an occurrence to escape notice, and many theories have been propounded to explain this relationship of two diseases clinically so different. These theories vary from the idea that the acute illness has reduced the bodily resistance to disease to the belief that the pathogenic virus of rheumatism uses the inflamed tonsil as its portal of entry, or that tonsillitis and polyarthritis are but different manifestations of the one great rheumatic disease, including in its symptoms chorea, endocarditis, and all the other diseases of the rheumatic chain. At the recent Sixteenth International Medical Congress at Budapest, Vosanyi and Lenart presented a communication on this subject in which they emphasized the necessity of careful examination of the tonsils in all cases of acute rheumatism. The authors pointed out the fact that a cursory and superficial examination of the throat was not sufficient, as in many cases of rheumatism in which the tonsils showed no superficial exudate they had found upon removing the glands a deep-seated purulent inflammation, a lacunitis. For this reason the speakers advised in every case of acute articular rheumatism an immediate and complete removal of the tonsils. In their experience such a procedure was followed by a prompt subsidence of the symptoms in the joints and a rapid convalescence of the patient. The operation of tonsillectomy during the acute febrile period of articular rheumatism appears at first sight to be a procedure of such great risk that its performance will probably not receive very enthusiastic sanction from the internists, especially those of them who have learned to use the salicylates in sufficiently large doses and have seen this prompt subsidence of the rheumatism under this treatment. When one considers, however, the serious and lifelong sequelæ of rheumatic fever, one is tempted to give ear to any treatment, no matter how heroic, which it is claimed will abate an attack of this disease. If it could be proved conclusively that rheumatic fever is due to absorption or infection from deep-seated suppuration of the tonsils, and that it can be cured by tonsillectomy, the treatment might receive many adherents.

News of the Week.

The Conference on Prevention of Infant Mortality of the American Academy of Medicine was held at New Haven, November 11 and 12, 1909. Dr. J. H. Mason Knox of Baltimore presided, and President Hadley welcomed the delegates. Dr. Knox laid emphasis on arousing public sentiment to insist upon suitable hygienic surroundings, adequate care, and proper diet for every new-born babe. Among the most important factors in this was the question of alcoholism in the parents. Dr. Clemens von Pirquet of Baltimore spoke on tuberculosis in childhood. He said that children infected during the first year usually died. The important point in infant prophylaxis was the separation from infected parents. If this could not be done the reduction of undue fondling and kissing was of importance. Dr. J. P. Crozer Griffith of Philadelphia spoke on sum-

mer diarrhea, the importance of breast feeding, and the difficulty in obtaining a clean milk supply. Dr. Alice Weld Tallant of Philadelphia urged more thorough education of young mothers and prospective mothers in the subject of infant hygiene. Dr. Caroline Hedger of Chicago urged shorter hours for working women and better sanitation and food during pregnancy. Dr. Alice Hamilton of Chicago said that the infant mortality in families of over four children was two and one-half times as high as in the smaller families. She advocated smaller families. Mr. Edward T. Devine of New York said that in the past forty years in spite of the increase in population and crowding the infant mortality in New York had decreased 43 per cent. The social economist's work consisted in efforts to reduce that portion of the mortality due to adverse social conditions. Dr. Ira S. Wile of New York, in speaking on milk depots, said that the duty of such an institution was not only the distribution of clean milk, but also the education of the mothers, especially as to the value of breast milk. The index of the value of a milk depot lay in the number of attendants who were nursing their babies. Dr. Charles P. Putnam of Boston described at length the evolution of the orphan and infant asylum, laying especial stress upon the value of the paid agent to visit children who had been put out in homes. Miss Lillian Wald of New York described the work of the visiting nurse. Dr. H. J. Gerstenberger of Cleveland also spoke on education of the mother and advocated the German method of offering prizes to the mother whose baby showed the greatest improvement within a given period. Dr. Woods Hutchinson of New York spoke on the influence of charities on infant mortality. He said among the chief causes were poverty and its children, ignorance and dirt. The doctrine of teaching contentment to one's lot was wrong. A great danger was the working of mothers just before and after labor. The founders of crêches and day nurseries must consider whether by making this possible they were doing good or harm. The giving of prizes to encourage mothers of the working class to bear large families was equally dangerous. Dr. Herman Schwartz of New York said that the reduction of infant mortality depended upon three factors—the care of the child before, during, and for at least a year after birth; the education of the parents, and the propaganda of breast-feeding and securing clean cow's milk.

At the conclusion the following was adopted:

"The task of preventing infant mortality is second to none in importance and should engage the best attention and effort of all individuals, lay and professional, and of every commonwealth and community. As looking toward the attainment of such prevention the American Academy of Medicine records its convictions in the following resolutions:

"First—Resolved that the present high rate of infant mortality is due to inherited debility or disease, improper environment and care, improper feeding, and communicable diseases, and is to a high degree preventable.

"Second—Resolved that the breast feeding of infants is, when possible, the only proper method, and that artificial feeding should never be substituted as a matter of choice.

"Third—Resolved that the reporting of all communicable diseases, especially of those commonest in society, to health boards, should be compulsory.

"Fourth—Resolved that the scientific instruction of the young in practical hygiene and sanitation and of mothers in the care and rearing of infants is an important duty resting chiefly on physicians, sociologists, school authorities, and boards of health."

As a result of the conference the American Association for Study and Prevention of Infant Mortality was organized at special meeting on Saturday morning, November 13, in Lampson Hall. Dr. F. H. Gerrish of Portland, Me., presided, and Dr. Charles McIntire acted as secretary. A constitution and by-laws were adopted and the following officers were elected: *President,* Dr. J. H. Mason Knox, Jr., Johns Hopkins Medical School; *First Vice-President,* Prof. C.-E. A. Winslow, biologist in chief of the Laboratory Research, Mass., Institute of Technology, Boston; *Second Vice-President,* Mr. Homer Folks, Secretary of the New York State Charities Aid Association; *Secretary,* Dr. Henry I. Bowditch of the Harvard Medical School, Boston; *Executive Committee,* the officers and Dr. Mary Sherwood of Baltimore, Md.; Dr. J. S. Neff, Director of Public Health and Charities of Philadelphia; Mr. Robert W. Bruere of New York; Dr. Helen C. Putnam of Providence, R. I., and Dr. John S. Fulton, Secretary-General of the International Congress on Hygiene and Demography of Washington. Baltimore was selected as the meeting place of the society. The meeting will be held in the autumn of 1910. Dr. Charles Richmond Henderson of the University of Chicago was nominated president for 1910-1911 meeting.

College of Physicians of Philadelphia.—The dedication of the new hall erected at Twenty-second and Ludlow streets at a cost of $300,000 took place on November 10 and 11. Fellows and guests of the college and candidates for associate fellowship assembled at 2 P.M. in the First Unitarian Church, at Twenty-second and Chestnut streets, and in procession marched to the entrance of the new hall, where the presentation of the new building was made by Dr. Wm. J. Taylor, Secretary of the Building Committee, and acceptance by Dr. George E. de Schweinitz, Vice-President of the College. The College was called to order in special meeting in Weir Mitchell Hall by the president, Dr. James Tyson, and addresses of greeting and congratulation were delivered by Dr. John S. Billings on behalf of the New York Public Library, Dr. Charles L. Dana on behalf of the Academy of Medicine of New York, Dr. Reginald H. Fitz on behalf of the Boston Medical Library, Dr. Wm. S. Thayer on behalf of the Medico-Chirurgical Faculty of Maryland, Dr. Robert Fletcher on behalf of the Library of the Surgeon-General's Office, and Dr. Frederick P. Henry, Honorary Librarian of the College. Associate Fellowship was conferred upon Dr. Archibald B. Macallum by Dr. A. P. Brubaker, on Dr. Oliver F. Wadsworth by Dr. George E. de Schweinitz, on Dr. Edward G. Janeway by Dr. James C. Wilson, on Dr. Charles L. Dana by Dr. Charles K. Mills, on Dr. Frank Billings by Dr. John H. Musser, on Dr. George W. Crile by Dr. William L. Rodman, and on Dr. Franklin P. Mall by Dr. George A. Piersol. Congratulatory telegrams from the Royal College of Surgeons of Edinburgh, the Royal College of Surgeons of England, and Dr. Wm. Osler were read. The dedicatory address was delivered by the President of the College, Dr. James Tyson, and the benediction was given by the Right Rev. Ozi W. Whitaker, Bishop of Pennsylvania. In the evening

a dinner attended by nearly 500 was held in the Bellevue-Stratford and toasts were responded to as follows: "The Old College and the New," by Dr. S. Weir Mitchell; "Libraries and Their Foundations," by Mr. Andrew Carnegie; "The College Library and Its Treasures," by Dr. W. W. Keen; "The College and Its Civic Relations," by the Hon. Hampton L. Carson; "The College and Its Traditions," by Dr. Arthur V. Meigs. On November 11 the hall was thrown open to public inspection and in the evening an address was delivered by Dr. S. Weir Mitchell, who discussed "The Relations of the College to the Public," and later there was an informal reception.

German Hospital Anniversary.—The celebration of the fortieth anniversary of the German Hospital of New York City was held on November 13, 1909. The German Consul General Franksen read a letter, signed personally by Germany's Imperial Chancellor, Bethman-Hollwig, saying that "his Majesty, the Emperor, has generously deigned to confer upon the President of the Medical Board of the German Hospital, Dr. Otto Kiliani, the Order of the Crown, and upon the two other members of the board, Dr. Rudolf Denig and Dr. Louis Peiser, the Order of the Red Eagle." The Imperial Chancellor's letter also said that Emperor William presented to the superintendent of the hospital a scarf-pin in the form of an eagle, consisting of a large emerald, surrounded by diamonds and pearls. President August Zinsser of the hospital also received the degree of Honorary Doctor of Medicine from the University of Giessen.

The Second International Food Congress was held in Paris, October 17-24, 1909. It was presided over by M. Reau, the distinguished Minister of Agriculture of France, who was supported by Professor Bordas, President of the Congress, and M. Paul Bolo, one of the founders. This year's Congress was devoted to the definitions of such operations as might be recognized in the manufacture of alimentary substances. The processes of manufacture and adulteration of many food stuffs and drugs were defined, and the question of what constituted a pure food and what an adulteration determined. One thing was very noticeable, namely, that it became plainer and plainer as the Congress progressed that there was hardly a substance in connection with the food supply, which was not subjected to some kind of sophistication or adulteration, and it became evident also, that if the means could be devised to prevent frauds in food, it would be an immense gain to every nation. It appeared to be quite common in some industries to employ skilled chemists with a view to reducing the quality of the food, while preserving its external appearance, and frauds of this kind were daily perpetrated. This more especially affected the poor, who were not in a position to judge of the purity of their food, or control it in any way.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission will hold examinations on December 11, 1909, for the following positions: Physician, Onondaga County Almshouse, $780. Trained Nurse, State Institutions, $420 to $600 and maintenance. Applications should be filed on or before December 4. For detailed circular and application blank, address State Civil Service Commission, Albany, N. Y.

Army Medical Corps Examinations.—The Surgeon-General of the Army announces that the first of the preliminary examinations for the appointment of first lieutenants in the Army Medical Corps for the year 1910 will be held on January 17, 1910, at points to be hereafter designated. Full information concerning the examination can be procured upon application to the "Surgeon-General, U. S. Army, Washington, D. C." The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training or its equivalent in practice after graduation. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible. The examination in subjects of general education (mathematics, geography, history, general literature, and Latin) may be omitted in the case of applicants holding diplomas from reputable literary or scientific colleges, normal schools, or high schools, or graduates of medical schools which require an entrance examination satisfactory to the faculty of the Army Medical School. In order to perfect all necessary arrangements for the examination, applications must be complete and in possession of the Adjutant-General on or before January 3, 1910. Early attention is therefore enjoined upon all intending applicants. There are at present eighty-one vacancies in the Medical Corps of the Army.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1910, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and must be received by the Secretary of the College on or before May 1, 1910. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award. Thomas R. Neilson, M.D., Secretary.

College for Emmanuel Movement.—Dr. Elwood Worcester, the founder of the Emmanuel movement, states that there is a move afoot to found a college and that $1,000,000 is desired for this purpose. The purpose is to provide a place where students of medicine, theology, and sociology may work together, and thus build up what Dr. Worcester thinks the movement proves the need for—specially trained men competent to practise. A periodical intended solely to discuss and present the movement is to be established, with headquarters in Chicago. It will be called *The Emanuel Movement Bulletin*.

New Jersey Vital Statistics.—The report of the

department of vital statistics of the State Board of Health of New Jersey for the month ending October 15 shows a startling increase in the number of infant deaths in New Jersey. From infant diarrhea the number was 362, the average from this cause during the preceding 12 months was 196. The deaths at the age of one year and less were 744. The total number of deaths in the State was 2,894. The report shows a decrease in deaths from infectious and contagious diseases and an increase in deaths from cancer. These were 147, as against 137, the average for the preceding 12 months. The suicides were 41, against the average 35 for the preceding 12 months.

The Radium Institute of America was formed at a meeting in the building of the New York Yacht Club recently. The purpose is to study radium, discover any radioferous deposits in the United States, and buy quantities of it in Europe for clinical use in the United States. It is the idea of the founders to establish a clinic in connection with some New York hospital, where radium treatment will be administered free to those needing it. The institute will take steps to protect the public from the false claims of patent medicine manufacturers that certain of their remedies contain radium, and will set a standard that those desiring to deal in radium commercially will have to live up to. Dr. Charles F. Chandler was elected *president;* Dr. Robert Abbe, *vice-president*; Prof. William Hallock, *secretary*; Prof. George B. Betram, *assistant secretary,* and Dr. Hugo Lieber, *treasurer.*

Amoy Free from Plague and Cholera.—The United States Marine Hospital Service reports Amoy free from bubonic plague and Asiatic cholera.

Dr. Charles Hoffman of New York has been elected Professor of Electrotherapeutics at the New York School of Clinical Medicine and the West Side German Dispensary.

Dr. G. H. Sumner of Waterloo, Iowa, for the past eight years health officer of that city, has been appointed Secretary of the Iowa State Board of Health.

Gifts to Charities.—The new Lawrence Hospital in Bronxville, Westchester County, N. Y., has received a gift of $150,000 from the founder, Mr. W. V. Lawrence.—By the will of Mrs. Franziska Speyer of Frankfort-on-Main, Germany, $2,500,000 was left to charitable institutions. This includes $250,000 for an institution for the study of cancer

New West Side Hospital Needed.—A committee of physicians was formed recently by the West End Association of New York to report on the need of a new municipal hospital on the west side of the city. The association also determined to bring pressure to bear upon the Board of Estimate to grant the appropriation of $32,500, voted last July by the Aldermen for the establishment of an improved ambulance service for the west side north of Fiftieth street. The bill for this improved ambulance service passed the Legislature last season and was approved by the Governor and the Mayor.

Gynecological Department for Sloane Maternity Hospital.—Through the generosity of Mr. William D. Sloane the Sloane Maternity Hospital is to have a seven-story addition to be erected on Tenth avenue and used as a gynecological department. The service will be under the charge of Dr. Edwin B. Cragin, and will be used for the purpose of instruction in gynecology in the College of Physicians and Surgeons of Columbia University.

A New Free Dental Clinic was opened on November 15 at the Worth Street Italian Industrial School of the Children's Aid Society. The clinic is under the auspices of this society and the New York Dental Hygiene Council of the Dental Society of the State of New York.

The Denver College of Physicians and Surgeons has ended its existence by the unanimous vote of the board of directors and the faculty.

The Tuberculosis "Preventorium" for Children which was opened last summer at Lakewood, N. J., announces total benefactions amounting to $700,000. The institution is intended for early cases of tuberculosis and the children of tuberculous parents in poor health. It is at present located in the cottage, the former summer home of ex-President Cleveland. During the summer ninety-two children were cared for in this building. Before next summer it is hoped that the institution will be so increased as to accommodate four hundred children. Dr. Alfred F. Hess is physician in charge.

The Metropolitan Life Insurance Co. has filed with the County Clerk, at Albany, a writ of certiorari issued by Supreme Court Justice Fitts and returnable before the Appellate Division of the Supreme Court, Third Department, in the matter of its application to Supt. William H. Hotchkiss of the State Insurance Department for approval of a plan to buy land upon which to maintain a tuberculosis sanatorium. Supt. Hotchkiss gave a decision denying the application on the ground that he had no power under the insurance law to permit such use of the funds of an insurance company.

New Dorp Infants' Hospital.—At the annual meeting of St. John's Guild, announcement was made of plans to erect a new building on the site of the guild's present Seaside Hospital at New Dorp, S. I., to accommodate the guild's larger activities in the care of sick mothers and children. About $225,000, it was said, would be necessary for this purpose. The amount will be raised by subscriptions for which appeals will be sent out in December. The report of the president was read, showing a total endowment fund of $105,083 at the end of the fiscal year, a total of 44,414 women and children carried on the guild's hospital boat, *Helen C. Juilliard,* and a total of 2,696 women and children treated at the Seaside Hospital, with but 51 deaths.

The Beth Israel Hospital of New York City has just created a separate and special Surgical Department for Diseases of the Nervous System, in charge of Dr. Ernest Sachs.

The British Medical Association will hold its next annual meeting in London, in July, 1910, under the presidency of Mr. Butlin.

The Western Illinois District Medical Society held its annual session at Quincy, Ill., Ocober 30, and the election of officers resulted as follows: *President,* Dr. J. H. Rice of Quincy; *Vice-Presidents,* Dr. Waldo Fisher of Alton and Dr. J. G. Franklin of Chandlerville; *Secretary-Treasurer,* Dr. W. P. Duncan of Jacksonville.

The Grand Traverse County (Mich.) Medical Society, at its annual meeting at Traverse City, elected the following officers: *President,* Dr. W. D. Mueller; *Vice-President,* Dr. E. B. Minor; *Secretary and Treasurer,* Dr. R. E. Wells.

The Birmingham Surgical and Gynecological Society was organized recently at Birmingham, Ala., with the following officers: *President*, Dr. B. G. Copeland; *Vice-President*, Dr. Gaston Torrance; *Secretary and Treasurer*, Dr. Edward P. Soloman.

The Alumni Association of the Lying-In Hospital.—At the stated meeting of the Alumni Association of the Lying-In Hospital of the City of New York, held November 9, 1909, at the Harvard Club, the following officers were elected: *President*, Dr. Asa B. Davis; *Vice-President*, Dr. Wm. Meloud; *Secretary-Treasurer*, Dr. Joseph E. Lumbard. Dr. Albert F. A. King of Washington, D. C., read the paper of the evening, "The Significance of Posture in Obstetrics."

Obituary Notes.—Sir William Thomson, Honorary Surgeon to the King in Ireland, died on November 14, 1909, aged 66 years. Sir William was born in Scotland, was educated at Queen's College, Galway, and Queen's University. He was created a Knight in 1897, had charge of Lord Iveagh's Irish Hospital in the South African campaign and was "mentioned in dispatches." He was an ex-president of the Royal College of Surgeons, Dublin, and held numerous official and honorary offices in connection with medical and surgical activities.

Dr. Gabriel Grant of New York City died at his home, November 8, 1909, aged 83 years. Dr. Grant was a graduate of William College, in 1846, and the College of Physicians and Surgeons of New York, in 1851. After a brief service in Panama, during which he organized the first American hospital there, he returned to New York to fight the cholera epidemic, at which time he was made Health Commissioner of Newark. For distinguished services during the Civil War, Dr. Grant was awarded the Congressional medal of honor. In 1863 he became medical director of Evansville Hospital and then surgeon in charge of the United States Army General Hospital, at Madison, Ind. He was a member of many societies, including the Medico-Legal Society.

Dr. George Seymour of Utica, N. Y., died at his home, November 8, 1909, aged 70 years. A graduate of the New York University, in 1865, Dr. Seymour spent his entire later life in Central New York, in which neighborhood he was one of the best known practitioners. He was at one time Health Commissioner of Utica, and was for many years visiting gynecologist to St. Luke's Hospital. He was a member of the Oneida County Medical Society and the New York State Medical Association.

Dr. Edward J. Hogan of New York City died at his home, on November 7, 1909, aged 71 years. He was a graduate of the College of Physicians and Surgeons in New York, in 1867, and was a member of the New York Academy of Medicine, the Medical Society of the County of New York, the New York State Medical Association, and the American Medical Association.

Dr. Cleophas Joseph Ducate of Cottonport, La., died at his home, October 26, 1909, aged 59 years. He was a graduate of the Medical Department of Tulane University in 1875, and one of the most prominent physicians in Louisiana, having been president of the Louisiana State Medical Society and a member of the Board of Supervisors of the Louisiana State University.

Dr. George Hunt of Bridgewater, Mass., died at his home, October 24, 1909, aged 54 years. He was a graduate of the Boston University School of Medicine.

Dr. Charles F. George of Goffstown, N. H., died suddenly, November 3, 1909, aged 68 years. He was a graduate of the College of Physicians and Surgeons of New York, in 1865, and was a member of the Hillsboro County and New Hampshire Medical Societies.

Dr. John Harvey Davisson of Los Angeles, Cal., died at his home, November 1, 1909, aged 60 years. He was a graduate of the College of Physicians and Surgeons of Baltimore, in 1876, and a former president of the California State Board of Health. He was a member of the Los Angeles County Medical Society, the California State Medical Society, Southern California Medical Society, American Medical Association, and was one of the organizers of the California Hospital.

Dr. Augustin F. Anderson of Lowryville, S. C., died at his home, November 2, 1909, aged 89 years. He was a graduate of the Atlanta Medical College, in 1845, and was a member of the Chester County Medical Society and the South Carolina Medical Association. In 1878 Dr. Anderson served one term in the South Carolina State Legislature.

Dr. William Thompson of Little Rock, Ark., died October 26, 1909, aged 80 years. He was a graduate of the University of Tennessee, in 1856, and a member of the Pulaski County and the Arkansas Medical Societies.

Dr. R. L. C. White of Nashville, Tenn., died at his home, October 30, 1909, aged 65 years. Graduated from the Jefferson Medical School, in 1869, he practised his profession for a few years in Lebanon, Tenn., and then retiring to become editor of the *Lebanon Herald*, he became one of the foremost literateurs of the South.

Dr. Harriette C. Keatinge of New York City died at her home, November 12, 1909. She was a graduate of the New York Medical College for Women, in 1879. After practising in Louisiana, Dr. Keatinge came to New York, in 1885. She was a member of the County and State Homeopathic Societies and the American Institute of Homeopathy.

Correspondence.

MOVING PICTURES OF MICROSCOPIC OBJECTS.

To the Editor of the Medical Record:

Sir:—In the last few weeks there have been various articles in the daily press, emanating from London and Paris, giving credit to a Frenchman for inventing a most wonderful machine—a cinematograph—by which moving microscopic pictures can be taken and then projected on the screen.

I wish to call attention to the fact that this machine is nothing new; that I invented it some thirteen years ago, and that I demonstrated the same as far back as 1897 to a private audience, among whom were Drs. Wm. N. Katzenbach, G. Lenox Curtis, E. Bradley, and J. H. Gunning, Mr. Hopkins, editor of the *Scientific American*, and many others. On July 31, 1897, the "micromotoscope," as I named the machine, was described and illustrated in the *Scientific American*, and some time later in *Photograms*, a London periodical, where due credit for the invention was given. Under my direction, the machine was later demonstrated at the Grand Central Palace at the Trained Nurses' and Pure Food Exhibition, where pictures of the circulation of the blood in the web of the frog's foot, rotifers in stagnant water, an ameboid leucocyte, typhoid germs, and many others were shown to over 10,000 people who attended the exhibition.

Since that time my original rough apparatus has been greatly improved and simplified, so that now moving mi-

croscopic pictures for scientific purposes can be easily taken. The latest demonstration of this machine took place at Chicago, June 17, 1909, when various photographs of microscopic objects taken with the micromotoscope were shown to an audience of 500 physicians of the National Eclectic Medical Association. As further evidence of my invention, I refer to the "Standard Dictionary" of the 1905 edition, where in defining the micromotoscope due credit is given me as its inventor. I, therefore, claim the credit of being the first to conceive this idea and perfect the machine.

Robert L. Watkins, M.D.
20 West Thirty-fourth Street.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE "NATION AND THE TROPICS"—ANESTHETICS—INFECTIONS OF INTESTINE—THE INDIAN CONFERENCE ON MALARIA—THE KING AT NORWICH HOSPITAL—COMMITTEE ON AFRICAN AND TROPICAL DISEASE—QUEENSLAND TROPICAL SCHOOL—MAGNIFIED MICROBES—LISTON PRIZE—OBITUARY.

London, October 29, 1909.

Your Ambassador presided on Tuesday at the opening of the session of the School of Tropical Medicine, and in introducing the lecturer, Professor Osler, spoke of him as an excellent example of what America could do with a Canadian when he was caught young. McGill University brought him out; he reached the climax of his fame at Johns Hopkins, and then retired into his dignified repose at Oxford.

Dr. Osler then delivered the inaugural address, subject "The Nation and the Tropics." He said the white man had partitioned one hemisphere, two continents, and a large part of a third. France controlled a tropical population of 36,000, Germany 12,000, the United States 800,000, the United Kingdom 330,250,000. The responsibility of empire had always been the making of a race. In dealing with subject races there were two problems—order and health. The first seemed a specialty of the Anglo-Saxon. If there were doubts about manners, morals, or religion, there were not about giving good health and freedom from pestilence and famine. Much had been done in the last twenty-five years in acquiring knowledge of the causes of diseases, but the task of prevention was only just begun. There were 400,000 deaths from fever in the Punjaub and a quarter of the total population suffered from malaria. The first clear demonstration of insect-borne disease was made by Manson and had greater significance than any other discovery. One was at a loss to know which to admire most, the accuracy of the experiments or the heroism of those who made them, all the time playing with death, some paying the penalty. In nine months Havana, the home for centuries of yellow fever, was cleared after the American occupation, and other great cities have had the same experience since. The possibility was in sight of exterminating one of the world's greatest plagues, which had cost millions of lives and at intervals stopped the commerce of half a continent. The lecturer then went on to tell the story of the Panama Canal; after which he said the three most important tropical diseases did not kill so many now as the two diseases of temperate climates—pneumonia and tuberculosis. To make our knowledge effective the problem to-day was organization. There ought to be an imperial tropical institute to look after the health of the empire with a highly trained staff ready to be sent hither and thither. This was no dream; the most useful work in British medicine during the last twenty-five years was the result of the Liverpool Tropical Missions. The possibilities existed in London for the greatest school of tropical medicine in the world if only London would rise to the occasion. For other missions millions were contributed; it was not too much to ask endowments for this. It behooved us to see that we were well equipped for the second great task of empire, to give the teeming millions that great blessing and necessary of life, health.

Your Ambassador said the lecture had impressed him with the madness of nations, which had great tropical dependencies and did not cultivate tropical medicine. They were blind to their interests—perhaps to their safety. There was no tropical sea where the British flag did not float, scarcely any land into which their people had not penetrated. Like Professor Osler, he had seen a flag which carried self-government sent to the most beautiful island of the Antilles, one of the most beautiful in the world, in danger of being driven out by the yellow flag of the pest house. To-day on the Panama there were 40,000 soldiers of industry attacking a task more colossal than any in the history of industry, working under conditions due to the study of tropical medicine. There was room for spending a good deal more money on that school.

The chairman of the committee of the school proposed a vote of thanks to the Hon. Whitelaw Reid, American Ambassador, for presiding, which was seconded by Sir P. Manson and carried with acclamation.

The paper at the Medical Society of London this week was by Dr. F. W. Hewitt, who discoursed on the need for legislation in regard to anesthetics and laid down the lines on which he though it ought to take place. I may summarize the paper as a plea that only duly qualified medical practitioners should be permitted to employ anesthetics. The contention is a reasonable one, in view of the frequent fatalities, not a few of which might, argued Dr. Hewitt, have been averted had a medical man been present. In regard to restriction, the position of dentists has to be considered and a plea has been put forward on their behalf. But Dr. Hewitt held that the restriction would raise the status of the dentist and strike a decisive blow at quack dental practice. He had made inquiries as to the conditions of dental practice in forty-eight towns, with a combined population of 2,138,130, and found in them one registered dentist to 4,435 persons. The majority of dentists had no partners nor assistants, and it is conceded generally that single-handed operating and anesthetizing is reprehensible. The only proper recourse is to call in a medical man.

There is now before the departmental committee of the Home Office a bill which deals with this subject. It proposes to make it a penal offense for any other than a registered medical practitioner to administer any drug or substance, whether solid, liquid, or vaporous, whether pure or mixed with another substance, for the purpose of producing unconsciousness during any surgical, medical, obstetrical, or dental operation. Exemption is made in favor of those acting under the immediate supervision of a registered practitioner and students under the supervision of teachers of dentistry. An outcry has been made in some quarters as to the expense which would be caused by the proposed restriction. But if the additional work were thrown on local doctors the question of fees would settle itself.

At the Hunterian Society Dr. S. Martin delivered the Hunterian lecture on the 13th inst., his subject being "Infective Processes in the Intestine." He spoke of the treatment of their effects and stated that vaccines of *Bacillus coli* gave remarkable results in some cases, but of course did not invariably succeed. He mentioned two cases of thrombosis in which excellent results had been obtained. He further said large doses were dangerous and gave rise to local reaction with swelling. His dose was from one to four million dead bacilli. Yet the rôle of *B. coli* was to counteract putrefactive bacteria. Both this and the lactic acid bacillus prevented putrefaction in boiled milk. Injected into the tissues it was pathogenic. Septicemia following enteric fever or cholera was due to *B. coli*, which set up an irregular type of illness, which might improve and relapse. Acting indirectly, it might cause disease.

The Imperial Malaria Conference which sat at Simla has concluded its work with the following recommendations: The appointment of a scientific investigation committee to be linked up with organizations in each province for dealing with (a) the distribution of malaria in India, (b) the epidemiology and endemiology of the disease, (c) the action of quinine and other remedies. 2. Determination of exact causes of death. 3. Practical measures for (a) extirpation of anopheles, (b) minor drainage operations, (c) restriction of wet cultivation near towns where a source of anopheles, (d) the introduction of fish into collections of water, (e) oiling small collections of water which cannot be filled up. 4. Detailed recommendations as to the use of quinine, with reference to which the conference advises that it be sold in quantities sufficient for a case as well as in small packets by all possible agencies, and special efforts made by a liberal commission to induce private vendors to engage in its distribution. 5. Education—(a) committees of officials and nonofficials under the new councils to spread a knowledge of the disease and the measures to take against it among the people. (b) this also to be taught in the

schools. 6. The local governments should be invited to make annual assignments of funds for malaria investigation and prevention.

The King on Monday laid the foundation stone of the new block for septic and infectious cases of the Norfolk and Norwich Hospital. This is the first of several buildings contemplated for the extension of this hospital, which dates from 1772, but the erection of the present building was begun in 1879, when His Majesty, then Prince of Wales, laid the foundation stone. The King, in reply to the address, referred to this visit and also a subsequent one in 1884, as well as his long residence in the county, and added that no greater blessings exist for the poorer classes than institutions which provide relief and care in illness, and any movements to extend them would always have his warmest support.

The Mansion House appeal on behalf of St. Bartholomew's Hospital, which was postponed in order not to conflict with the Sunday and King's Funds collections, has been issued this week. It is endorsed by the Prince of Wales, as president, the treasurer, the Lord Mayor, the Bishop of London, and many others. Old Barts is endowed and does not often ask for aid from the public, but in these sad times its investments have yielded less, while expenses have increased. We look upon it as a city institution, for it has remained within the city boundaries for 800 years, and its work is known throughout the world. The bank and the great city companies are heading the list of contributors.

The Colonial Secretary has appointed the advisory committee on medical sanitary questions connected with tropical Africa. It is to consist of Sir Patrick Manson, Sir R. Boyce, Drs. W. T. Prout,. Theodore Thompson, W. J. Simpson, and J. K. Fowler, with three civil servants from the Colonial Office, though of what use these three may be, except the one to be secretary, it is not easy to guess.

The Medical Officer of the London County Council, in a further report on the epidemic of scarlet fever last June, says no reasonable doubt can be entertained that it was due to the milk of a particular farm. But how that milk became infected is not quite so clear. It has, however, been shown that when the milk began to show infectivity there was added to it the milk of three recently calved cows, the calf of one of which died after being suckled by the mother for three or four days. Further, all three of these cows and some others on the farm were at the later inquiry shown to be affected with the condition known as "Hendon disease," since that eruption on the udder and teats was described in 1885 on some cows at Hendon by Sir W. Power.

Dr. Anton Breinl of the Liverpool Tropical School, who was a member of the yellow fever expedition to Brazil of 1905, has been selected to go to Queensland and take charge of the newly formed tropical school of medicine there.

The Liston prize of the Edinburgh Royal College of Surgeons has been awarded to Mr. Robert Jones of Liverpool Royal Infirmary.

A Paris correspondent writes that M. Comandon (whose work on the ultramicroscope is well known) has reproduced magnified images of microbes on the cinematograph and shown them "moving, feeding, and fighting." The trypanosomes of sleeping sickness "were displayed on the screen as large as eels."

Dr. Edward Clapton, who died in his eightieth year on September 28, had been retired for several years, but had filled during a long life a great position in the world of medicine and letters. He was a St. Thomas's student. In 1857 he took the M.D. Lond. and F.R.C.P., but the following year, having been appointed assistant physician to his hospital, he joined the sister college, of which he was elected Fellow in 1870. He remained on the staff of his hospital and a teacher in the school until his retirement, and elder members of the profession retain his memory as a successful and reliable consultant and an amiable, most lovable man. Besides medicine he was deeply interested in Biblical studies and wrote on some abstruse questions which critical authorities considered he decidedly elucidated. He published a volume on the "Precious Stones of the Bible," of which he made a collection of specimens, as well as other interesting articles, for his museum. He also published a "Life of St. Luke," a subject most congenial to him. He was a member of various learned societies and consulting physician to many hospitals and other charitable institutions.

THE EIGHTY-FIRST CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS.

(From Our Vienna Correspondent.)

POSTAPPENDECTOMY SYMPTOMS—TUBERCULIN IN PROGRESSIVE PARALYSIS—RETROGRADE AMNESIA—CEREBRAL ARTERIOSCLEROSIS—THE OLFACTORY CENTER—ALCOHOL IN FACIAL NEURALGIA—CENTRAL VISION AND THE CORPUS CALLOSUM—CHEMISTRY OF THE BRAIN—NODULAR KERATITIS—RECESSUS ETHMOLACRYMALIS—OTITIS MEDIA AND THE SENSE OF SMELL—INFECTION OF LABYRINTH—OTOSCLEROSIS.

SALZBURG, September 26, 1909.

In the section for surgery the Vienna surgeon, Dr. M. Jerusalem, spoke on discomfort following appendix operations and said that the patients often complained afterwards of serious discomfort similar to that from which they had suffered before the operation. We were in the habit of blaming all postoperative discomforts in the region of the wound to peritoneal adhesions. By means of painless manipulation of the abdomen the peritoneal adhesions might be broken down and firm, hard scars softened. There could, however, be no doubt that nervous and vasomotor injuries occurred from the insult to the peritoneum and might result in the most anguishing postoperative symptoms. The redness of the skin remained, in the right renal region pain was felt, and without there being any evidence of disease of the right kidney blood was found in the urine. These postoperative symptoms were found more often after the mild interval operations with relatively few appendicial symptoms than after operations during an acute attack of appendicitis. The routine excision of the healthy appendix "when the abdomen is open" might better be omitted. The chief point was prophylaxis. Modern functional after-treatment (early getting up) might prevent the formation of adhesions, as well as nervous and circulatory lesions.

In the section on neurology and psychiatry Professor Wagner-Jauregg of Vienna reported on the injections of tuberculin in progressive paralysis. Basing his work on the long-known fact that chronic brain diseases might be improved by an intercurrent acute febrile infection, for example by a sudden erysipelas, Professor Wagner made a systematic study of the effect of injecting large doses of tuberculin into paralytics and as a result saw the process come to a standstill.

Dr. K. Neisser, director of the Bunzlaw Provincial Sanitarium, reported two mental cases. The first case was in a woman of sixty, whose severe psychosis dated back eight years to the bite of a viper. This was the first case of the kind known. Considering, however, that the symptoms were such as one saw as a rule only following intoxications, the etiological connection could be stated definitely and on these grounds she had received accident insurance. The second case was one of epileptic stupor with retrograde amnesia in a case of combined hysteria and epilepsy and was of interest in that memory was lost, not only for the time of the attack but during the time immediately preceding the same. Cases had often been observed with retrograde amnesia for a few hours or days. In this case, however, the loss of memory was complete for a period of two and a half years.

Arteriosclerosis and its relation to brain disease was the subject on which Dr. Alfred Lustig of Franzenbad spoke. He called attention to the unquestionable increase in brain diseases resulting from arteriosclerosis. This fact was of especial significance, as cerebral arteriosclerosis was not merely the physiological representation of a malady peculiar to men of advanced age, but also attacked men in the best years of their usefulness. Sudden affections of the power of speech, even complete dumbness, word deafness, mind blindness, loss of the power to read or to write, even outspoken psychoses usually associated with paralysis of various members, sudden death from apoplexy, as they appear daily in the reports of the newspapers, were the disastrous sequellæ of cerebral arteriosclerosis. Early diagnosis, as it is possible to make it in this day, and proper scientific prophylaxis and therapy, were able not only to relieve but to postpone the onset of these conditions for many years.

The olfactory center was the subject of an address by Dr. Halsehek of Gräfenberg. He said that this center was much less developed in man than in many mammals, and that there existed a great difference of opinion as to where the sense of smell was located in the human cortex. In order to clear up this uncertainty he had studied with care the olfactory lobes of

many mammals, and had discovered a new cerebral center for smell in the anterior end of the so-called lobus pyriformis. This olfactory center was absent in the lower mammals among which other portions of the brain were greatly developed for the sense of smell, as, for example, the hippocampus. Among the higher mammals, however, as in the dog, and especially in many bears, it was present. The same structure could be found in the human brain, in the so-called uncus of the temporal lobe. The author considered this portion of the brain to be the olfactory center in man as well as in the lower animals and pointed out that this fact coincided with previous clinical and anatomical observations.

Privat Dozent Dr. A. Blum of Vienna spoke on the subject of alcohol injections for facial neuralgia and reported the results of four years' experience with the injection of 80 per cent. alcohol, sometimes at the point of exit of the trigeminal nerve from the base of the skull, sometimes in the peripheral nerve itself. The results were more lasting than either excision or tearing out of the nerve, the relief having lasted in his twenty-four cases from ten to seventy-two weeks.

In the section on physiology Professor S. Exner of Vienna spoke on the association between the corpus callosum and central vision. The Japanese student, Kisaku Yoshimura, had carried out some investigations under Professor Exner's directions in the Vienna Physiological Institute in order to learn the connection between the corpus callosum and central vision. It had already been shown by Imamura that the hemianopsia caused by destruction of one hemisphere in a dog would disappear again in the course of days or weeks under the mediation of the fibers in the corpus callosum. It did not disappear, however, if, besides destroying the hemisphere, the corpus callosum was cut through and the returned vision again disappeared when the corpus was cut. Yoshimura had now shown that it was the posterior fibers only which were involved in this and that the action was absent if the anterior part of the cortex only was injured. The fibers were recognized as belonging in all probability to those running to the occipital lobes and not those from the optic ganglia to the corpus callosum.

In the section for applied chemistry S. Frankel spoke on the chemistry of the brain. By extraction experiments the author had learned that the human brain was two-thirds composed of extractive substances, and but one-third of albumin. The former varied in the same species of animal with the development of the individual, and in different species it differed tremendously; the youthful brain was relatively poorer than the adult one. The great variety of these extractives (lipoids) and their variations in different organs and animals, might possibly throw some light on their significance for specific immune sera.

In the ophthalmological section Dr. E. Wahli of Frauenfeld reported on nodular keratitis, which he said his researches proved was tuberculous. He made this statement on the grounds of exact histological and clinical investigations and positive general and local tuberculin reactions, from which he stated that this previously obscure disease was proved to be tuberculous. He reported a case.

In the section of diseases of the nose and throat, Professor Dr. L. Grunwald of Munich, by means of many drawings, photographs, and anatomical preparations, described the discovery of the recessus ethmolacrymalis, a previously unknown cavity between the anterior part of the ethmoid bone and the orbit, and explained its development. From the history of a patient the author demonstrated the significance of this cavity in diseases of the neighborhood and for the proper interpretation of a previously obscure syndrome.

The influence of otitis media on the sense of smell was the subject of a report by Professor Viktor Urbantschitsch of Vienna in the section on diseases of the ear. He stated that loss of olfactory sense could follow abscess of the temporal lobe following otitis media. In such a case he found a continuance of the olfactory lesion after healing of the abscess, from which he sought to learn to what extent ear inflammations and the sense of smell were associated. In thirty cases of unilateral otitis media he found twenty-two to have affections of the sense of smell in the nostril on the side of the diseased ear, in sixteen a decrease and in six an increase of olfactory sensitiveness. That there was a real association was shown by two patients in whom the loss of smell sense noted during the otitis media improved when the latter healed.

Dr. Otto Mayer of Gratz demonstrated by many pictures of histological preparations that an inflammation of the labyrinth could occur during the course of an otitis media by diffusion of metabolic products found in the middle ear through the fenestal membrane. This was quite similar to the spread of a conjunctivitis to the eye through the cornea.

Dr. Emil Fröschels of Vienna reported the discovery of a new symptom which appeared to serve for the diagnosis of otosclerosis, a condition which previously it had often been difficult to diagnose definitely. The symptom depended upon the observation that otosclerotics stood delicate manipulations of the external auditory canal much more easily than other patients. Careful investigation of many of these cases showed that the ticklishness was much reduced. The author believed that with the aid of this new symptom it would be possible often at the very first examination to differentiate otosclerosis from harmless forms of ear disease.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 4, 1909.

Prognosis and Treatment of Renal Tuberculosis.—R. F. O'Neil says that the prognosis depends considerably on the promptness with which the diagnosis is made and the accuracy with which the indications for operation are met. Statistics of various authors are presented. It would seem that the prognosis in early unilateral tuberculosis is very good, and also very good in advanced cases when confined to one side. Mere climatic and hygienic measures are of value only if after nephrectomy, cystitis persists. Before operation they are a waste of time. At autopsies caseous nodules are found which may never have given symptoms, but they are latent and the cases cannot be considered as cures. There is no evidence that tuberculin is of value, though it may prove a useful weapon in bilateral tuberculosis. In general, the condition should be treated by removal of the kidney and the ureter if involved, assuming that there are no contraindications in the condition of other organs. Obstinate secondary bladder involvement calls for the use of the Roosings method of instilling 50 c.c. of a 6 per cent. aqueous solution of carbolic acid at 95° F. after the bladder has been cleaned of pus. Morphine is called for, as the pain is intense. Instillations are made daily at first, but the interval is gradually lengthened as the urine gets clearer to every three or four days.

Direct Transfusion of Blood.—A comparison of methods is made by J. C. Hubbard and A. B. Kinpton, who commend the cannulæ of Levin and Elsberg. In general, they find the operation conditioned in difficulty on the situation of the arm. After the cannula with the radial artery has been introduced into a slit in the side of the vein and tied in place, the authors find it advantageous to divide the vein distal to the cannula to give more slack and to prevent the bending of the vessels at an acute angle as they come out of the two incisions. The disadvantages of the Crile method are that the vein is generally of greater caliber than can be used. The walls of the veins have to be folded on themselves in order to pass through the cannula, thus reducing the size of the opening through which the blood is to flow. The great objection of this latter fact is the difficulty of determining whether or not blood is actually passing from donor to recipient.

New York Medical Journal, November 6, 1909.

Intramuscular Injections in the Treatment of Syphilis.—V. C. Pedersen prefers a 66 2-3 per cent. of the salicylate of mercury in liquid albolene combined with an hydrous lanolin. The mixture is of a molasses consistency, and does not require to be shaken before using. One c.c. of this solution contains 10 grains of the salt. The less the bulk of the fluid injected the less is the pain. The gluteal muscles should be relaxed before the injection is made. Embolin will be less common with the mixture advocated because it is semisolid and coheres strongly. A larger needle is necessary, however, and this increases the tendency to bleeding, but this is a trivial matter.

The Influence of Hydrogen Peroxide on Hydrochloric Acid Secretion.—E. H. Goodman finds this remedy an excellent one in hyperchlorhydria. From one to two drams of a 3 per cent. solution in a glass of water. Weaker solutions seem to be inefficient. The remedy is best taken after meals. The above dose may be doubled if necessary. The claim of the author as to the reduction of acid excess is substantiated by the results of chemical tests of stomach contents before and after taking the remedy.

Attic Suppurations.—M. J. Ballin makes a plea for the more frequent employment in suitable cases of intratympanic operations in chronic middle ear suppurations. Cases which are complicated with the formation of granulations and polypi arising from the upper tympanic space, and in which the probe reveals the presence of necrosis of the ossicles or of the surrounding bony walls, usually require operative interference. In the chronic suppurations in which granulations and polypi are seen to protrude into the tympanic space, it is most essential that they be removed. For this purpose, one may resort to the wire snare, to the various sized ring knives, or to the small spoons or curettes bent at different angles. As these various manipulations cause quite some pain, it is generally advisable to instill a few drops of a 10 or 20 per cent. solution of cocaine into the ear for from five to ten minutes. Or if the growths are very large we may inject a 1 per cent. solution of cocaine directly into them. The writer has also found the injection method of Neumann, for local anesthesia, most excellent for the removal of these polypi, as well as for all intratympanic operations. Having thoroughly removed the granulations of polypi, it is well to touch the roots with a little trichloracetic acid, and then to allow the patient to use a mild antiseptic instillation such as hydrogen peroxide for some time. In some cases in which the granulations are very small, touching them with trichloracetic acid, pure carbolic acid, etc., is sufficient to make them shrink. If the growths have disappeared and the discharge still continues we must resort to the local medication of injection as already detailed. The author is convinced that attic suppuration is the causal factor in keeping up many ear discharges. If after the exenteration of the upper tympanic space the discharge continues unabated for several months, resort to the radical mastoid operation may be called for.

Journal of the American Medical Association, November 6, 1909.

Gastric Cancer Diagnosis.—P. K. Brown, San Francisco, says that it is surprising that the fact presented by Rudolf Schmidt from Neusser's clinic in 1906, regarding the presence of the Boas-Oppler bacillus in the stools in cancer of the stomach, has excited so little attention in the profession. Schmidt found that the bacterial examination of the stools by the Gram stain under normal conditions revealed very few organisms, the Gram-negative colon group vastly outnumbering any Gram-positive organisms. A stool that with Gram's method showed bacilli of uniform size far outnumbering other organisms, he regarded as Gram-positive. Occasionally a stool is encountered in which Gram-staining organisms, chiefly cocci and nonuniform bacilli, are found in large numbers, and these are not Gram-positive in the sense that the predominating organism is a well-staining uniform one. He claims that many organisms have been mistaken for the Boas-Oppler one, which has served to put the relation of the Boas-Oppler organism to cancer in a considerable doubt. Certainly hereafter all the deductions about the relation of the organism to cancer must be made on an absolute determination of what is the Boas-Oppler bacillus. Brown's own findings thus far in a series of cases of cancer of the stomach, in which the diagnosis was confirmed by operation or autopsy, have failed to show any cases in which the stools were other than Gram-positive, and in no case of acute or chronic ulcer has the stool been other than Gram-negative on repeated examination. He gives a brief abstract of four cases in which the bacteriological examination was made, but not depended on, in the clinical diagnosis of ulcer of the stomach, but in each of which the operation or autopsy confirmed the finding of the diagnosis which would have been made by trusting in the bacteriological examination. The clinical diagnosis of ulcer was entirely justifiable from the symptoms and hereafter he will take more interest in this test than heretofore.

Serum Diagnosis of Syphilis.—Hideyo Noguchi presents the analysis of 2,406 blood serums by the complement fixation test. The main difference between his system and the Wassermann system lies in the use of a known quantity of amboceptor in his test, while in the Wassermann method we meet the difficulty that human serum may contain anywhere from 0 to 20 units of natural hemolysin (amboceptor) capable of inducing hemolysis with the sheep's corpuscles. With his method also he claims it is possible to preserve the various reagents, such as antigen, amboceptor, and, if necessary, complement, in stable form dried on filter paper and then titrated ready for use. The quantity of blood necessary for the test is very small, only a few drops, inactivation is not necessary, and the blood must not be fresh. The ease with which certain of the reagents can be produced is the factor; in his system human corpuscles are used and the patient's own cells can be utilized. In all other methods it is necessary to have a fresh supply of corpuscles always on hand. He shows the results in 244 cases of known syphilitic or metasyphilitic conditions in which the Wassermann method and his are contrasted, which he thinks prove his test as reliable as the other and its greater delicacy. The greater percentage of positive reactions which his tables show is not due to undue sensitiveness of the method, but to the elimination of the error of using too great a quantity of amboceptor.

The Precipitin Tests for Syphilis.—H. S. Wieder and E. M. L'Engle have studied the precipitin reaction tests which have been proposed as substitutes for the Wassermann and other deviation of complement tests, and report their experiments. Five different sets of experimnts were performed on 54 individuals. The following aqueous solutions were employed: 1 per cent. aqueous taurocholate of sodium, 1 per cent glycocholate of sodium, 1 per cent. lecithin, 1 per cent. taurin, and distilled water. Eleven patients suffered from secondary syphilis, 5 from tertiary syphilis, 17 from paresis, 1 from tabes, and the rest were divided nearly equally between sufferers from various nonspecific disorders and practically normal individuals. Altogether 253 observations were made, but only those made before the end of 18 hours were utilized, the others being found unreliable. The experiments consisted in adding one drop of serum to seven drops of the reagent and observing the effects some hours later. In the majority of cases the experiments were set up alternately by one of them and the observation made by the other, the one observing having no knowledge of the case studied. With the taurocholate, glycocholate, and taurin solutions a positive reaction consists in the formation of a flocculent tenacious precipitate, not dissolving on agitation, while with the lecithin the positive reaction is one in which the emulsion separates with dense central clumps and clear or almost clear supernatant liquid. In all the series the parasyphilitic cases gave most positive results, but the differences in other respects were not such as to indicate any great diagnostic value for the tests. This conclusion is also reached by the authors, as they say none of these tests give the practitioner a short road to the diagnosis of syphilis. They may be of some scientific interest, especially on account of the high proportion of positive results in parasyphilitics, but the proportion in nonsyphilitics is too high to make the test of any value.

Pyloric Stenosis.—S. Stillmann gives an analysis of the reported cases of pyloric stenosis in infants which he has collected as occurring on the Pacific Coast. He does not entirely agree with Koplik in classing it so closely with pyloric spasm. The latter, he thinks, occurs later than the hypertrophic stenosis and is the condition present in those cases of alleged hypertrophic stenosis in which the symptoms begin after the first two months or so of life and in which the patients recover under medical treatment. True stenosis is, he thinks, the result of a congenital abnormality of development. It is incomprehensible that such a tumor should be the result of any postnatal irritation in the first two or three weeks of life. He believes that in true stenosis there is always, or almost always, a tumor, and if more frequently sought for, especially with an anesthetic, it will be found. Infants stand an anesthetic as well as adults if not better. In the less-pronounced cases, however, in which the lumen of the pylorus is less altered, the tumor may not always be felt and may disappear under an anesthetic. It is not well enough appreciated also that infants stand surgery very well, especially in the first six weeks of life, and he disagrees with those who would reduce the child's vitality by starvation and trust to lavage, etc. The total number of cases he has to report is 27. The records were obtained by letters sent to representative physicians and surgeons who have favored him with the history of their cases. None of the cases dated prior to that of Barbat in 1904. Of these 27 cases the diagnosis was verified by post mortem or operation in 15. Of the remaining 12, the diagnosis in 7 was made by men of the highest standing and experience; in one of these operation was urged, but re-

fused, and the child died. In 2 others a tumor was present. The remaining 4 he classes as doubtful. One of the infants is dead and one is a very recent case. Eleven patients were operated on, of whom 9 recovered and 2 died; 16 were treated medically, with 9 recoveries and 7 deaths. Subtracting the 4 doubtful cases and 1 in which no tumor was found at operation, there are left 22 undoubted cases of hypertrophic stenosis. Of these, 15 infants recovered and 7 died; 10 were operated on and 12 were treated medically. Of those operated on 8 recovered and 2 died. Of those treated medically 6 recovered and 6 died. Of those recovering after operation all are now healthy children. Of the 6 survivors of medical treatment 1 at the age of 5 years is compelled to live on liquid diet, 2 are very recent cases, having been under treatment, 1 one month and 1 ten days. One child at the age of 5 months weighs 7½ pounds and operation has been considered but not advised. One at 6 months weighs 13½ pounds, and 1 at 7 months weighs 9 3-7 pounds. The 10 patients treated surgically were operated on by seven different surgeons, none of whom, he feels sure, would lay claim to more than average skill and experience. The results are less the sequel of surgical technique than of intelligent and enlightened judgment on the part of medical practitioners. So far as the operation of choice is concerned it seems to Stillman to need no argument to prove that posterior gastrojejunostomy, while not ideal, succeeds and can be done more safely and quickly by the average surgeon than any pyloroplastic operation. Whether the pylorus in some cases recovers its patency and the artificial opening closes or not does not affect the main issue in his opinion. The babies so treated are within a month in normal condition, while most of the medically treated ones are still suffering. Stillman believes that cases of pure pyloric spasm ought to be in most cases differentiated from all but the mildest cases of hypertrophic stenosis and that they should probably never be treated surgically. He says: "I think that medical treatment should be given while there is a reasonable doubt as to the diagnosis, in cases of hypertrophic stenosis plus spasm, in which no tumor can be demonstrated, but thereafter medical treatment should not be persisted in if the infant is losing ground; that control of vomiting in these cases does not mean cure, and that gastroenterostomy does not mean cure in at least nine out of ten cases, and that it is not so much a question of necessary operation as of unnecessary suffering, danger, and death."

The Lancet, October 30, 1909.

A Recent Case of Typhoid Spine.—C. J. Arlson reports the case of a man of 28 years who went through a typhoid course and who three months later was seized with severe pain in the back. The pain returned three days later, and during subsequent days he suffered from pain in the back in getting out of bed each morning, the pain wearing off after exercise. The condition grew steadily worse, and he was finally readmitted to hospital. In the next few weeks there were two periods of high fever. In three months the pain had practically ceased, but there was a marked rigidity over the dorsilumbar spine, pain on jarring the spine, and deep tenderness over the transverse processes of the first and second lumbar vertebræ. A radiograph showed much thinning of the intervertebral disk, with signs of necrosis in the vertebræ and many osteophytes around them. There was a marked Widal reaction. He eventually recovered completely. The author describes the general symptomatology of the typhoid spine, and says the conditions can be explained only by the invasion of the spinal tissues by the typhoid bacillus. The chief symptoms—pain and rigidity—must be due to acute inflammation of the periosteum and spinal ligaments, hence the name perispondylitis. In other instances there may be also an osteomyelitis of the vertebral bodies, sometimes causing a permanent kyphosis.

On Certain B. Coli Infections.—J. C. Briscoe says that various organisms, among them the *B. coli,* can leave the body by the urine without impairing the vitality of the genitourinary tract. The route by which these bacilli gain access to the urine is still a matter of dispute. Most of the *B. coli* cases occur in constipated patients, and most of them are in women. In these cases the urine is paler than would be suspected from its specific gravity, is often strongly acid, and is not clear and translucent. If it filters clear there is no appreciable quantity of *B. coli* present, but under technical methods described by the author many specimens will be found to contain it. Most of the instances occur in women, and some pathologists go so far as to say that in women the condition is of no importance. At times constipation is the only abnormality noted, but at other times there may be headache, slackness, and malaise. Confinement to bed may cause the passage of the bacilli. They may occur at times in a condition of health, and again be absent in the same subject. The author gives a series of histories of cases illustrating clinical variations in these respects. Treatment in the milder cases calls for the relief of any fever if present, a hot bath, a mercurial purge, rest in bed, and reduced diet. In more obstinate cases an intestinal antiseptic should be given, such as creosote or minute doses of calomel (1/20 gr.). Some prefer the lactic acid bacillus given internally. The urine should be kept alkaline. In the most obstinate cases the vaccine treatment is recommended.

The Selection of Patients for Spa Treatment.—N. Wood passes in review the most notable of the French and German spas and compares the two classes. The principal aim of the spa treatment is the furtherance of metabolism and the promotion of exertion. The treatment consisting as it does of the specialized use of what are known as natural remedies, is to be considered in relation to patients who cannot or will not employ these remedies at home, or who for some reason are not amenable to drug treatment. Though spa treatment is often only an alternative for other methods, it is preeminently suitable for cases on which it is desirable to concentrate a number of differing influences. Spas may be used for prophylaxis, but climatic stations are to be preferred for convalescence. Whenever there is a suspicion of visceral disease a reexamination of the patient should be made immediately before his departure. The best results from balneotherapy are obtained in the middle-aged and in young adults, while children and old people are more benefited by climatic influences. Only by the most careful application of general principles can patients be properly selected for spa treatment, for though it has contributed much to the art of healing, it has not added a single specific to the science of medicine. The maxim *noncurative qui curati* applies with special force to those who are sent away from home. Full benefit can be expected only when the patient can leave business and domestic worries behind and can face with equanimity the cost of treatment and of the amenities of spa life.

British Medical Journal, October 30, 1909.

Congenital Pyloric Stenosis Successfully Treated Without Operation.—The child whose case is recorded by E. M. Pearse came under observation when she was three weeks old. All food disagreed with her, and after examination a diagnosis of congenital pyloric stenosis was made on the following grounds: (1) vomiting of a projectile nature almost immediately after food was taken with the absence of any gastric disturbance; (2) loss of weight; (3) constipation; (4) visible peristaltic movements in the epigastrium culminating in a vomit; (5) relief of the symptoms for a day or two after a change of food. She was placed on the following treatment: (1) daily washing out of the stomach; (2) small feedings, an ounce and a half at a time, of peptogenized milk and water, half and half; (3) half a teaspoonful of "purgen" at night to relieve the constipation. She was also given daily a small amount of Keeler malt extract with cod liver oil. From this time the child began to improve. By the end of fifteen months she had gained from 7 lbs at birth to 15½ lbs. At the end of the time mentioned she was doing well in every way, though she could not quite manage the diet of the ordinary child for the corresponding age. The author thinks the points of interest in the case are: first, most, if not all, the recorded cases of the lesion named have been in male children; second, the case was under medical observation from birth; third, definite improvement did not permanently set in till the child was six months old, although the spasm usually passes off at an earlier date; fourth, there were never any convulsions due to the absorption of stagnant material in the stomach; fifth, the child was kept out doors constantly, and, sixth, she slept from 18 to 20 hours out of the twenty-four.

Seven Cases of Appendicostomy for Various Forms of Colitis.—The series of cases detailed by F. C. Wallis comprised three of ulcerative colitis, two of membranous colitis, and two of mucomembranous colitis. All but one of hemorrhagic colitis recovered. This case died after some weeks, and the author does not believe that the operation in any way benefited the patient. There was marked ulceration of the small as well as the large bowel. A fact generally borne out by autopsies is that the continuance of fluid motions largely composed of blood after appendicostomy and after the large bowel has been irri-

gated means that there is some ulceration of the small bowel as well. All the three cases of ulcerative colitis were greatly benefited. The first case got well right away. The second was entirely cured in a few weeks. The third, which was of some years' standing, eventually got practically well, but has to be very careful as to her mode of life. Otherwise there is some return of the former trouble. The two cases of mucomembranous colitis were greatly benefited.

Fulminating Appendicitis.—H. R. Butler bases his statements on the findings in four out of 52 cases of appendicitis seen in a little more than three years. The first two cases were operated on after signs of peritonitis had set in, in both cases just under 48 hours after the first symptom had occurred, and both died. They had absolutely general peritonitis, and in the first case the appendix was found broken off from its attachment to the cecum. The last two cases were operated on as soon as the arrangements could be made after seeing the patients—about six hours after the first symptom. In these the operations were simple enough, and the patients made uninterrupted recoveries. In each the appendix was just short of gangrenous. The author believes that volvulus is the cause of gangrene in all cases when it happens in so short a time after the first attack. The gangrene forms very rapidly, and there is not time for adhesions to form to shut off an abscess. If an operation is not performed in the first few hours we shall surely have general peritonitis. Volvulus may develop in any case in which the appendix lies free in the abdomen, but not when it lies in the rectocecal fossa. In doubtful cases the absence of the ordinary cecal sounds are suspicious, indicating that the ileocecal sphincter is held in a state of chronic contraction owing to powerful irritation in its immediate neighborhood. Another significant sign is the failure of flatus to pass with an enema. On opening the abdomen in these cases the appendix is found greatly swollen, congested, and plum colored, quite free from adhesions, except at its junction with the cecum, where it is constricted. It lies transversely under the cecum so that the mesoappendix is twisted on itself, and has to be manipulated with great care to avoid rupture while the cecum is being brought around into the wound so as to allow the removal of the appendix.

Pneumococcus Invasion of the Throat, Followed by Pleuropneumonia and Appendicitis; Operation; Recovery.—W. E. Peacock and W. Osler report the case of a boy aged 11 years with a sore throat and fever. There was a slight irregularity of the heart and a faint bruit. The tonsils and pharynx were congested, and the former enlarged, as were also the glands at the angle of the jaw. A swab culture revealed many pneumococci. The boy did well for a week, when he relapsed, and a pleurisy was detected at the base of the right lung. There was also much radiating abdominal pain. Later on appendicular abscess formed, and the dullness reached over to the left side. An opening was made in the right flank, and a counter-opening in the left. Much foul pus escaped, and the wounds were drained. The patient was kept in the open air. He did well for a while, but later there were evidences of pus accumulation somewhere, though under anesthesia only a fluctuation could be discovered high up in Douglass's pouch. On the night before the day on which an operation was to be done there was a bursting of the abscess into the rectum. From this time on recovery was uninterrupted. The entire duration of the illness was twenty weeks.

Berliner klinische Wochenschrift, October 18, 1909.

Proteolytic Ferment in Infant's Feces.—Czekkel studied the stools of a series of healthy and ill infants for the presence of proteolytic ferment. Healthy children, cases of acute indigestion, chronic indigestion, and premature infants were studied on various diets, and with normal, slimy, mucopurulent, and soapy stools. In every case proteolytic ferment was present. In a series of specimens of meconium also the ferment was always present.

Deutsche medizinische Wochenschrift, October 21, 1909.

The Westphalian Epidemic of Acute Infantile Paralysis.—Krause has studied over one hundred cases of anteriopoliomyelitis with eight autopsies in the recent epidemic in the neighborhood of Hagen. The youngest case was four and a half weeks old, and the oldest fifteen years. More than 90 per cent. showed initial gastrointestinal symptoms. Two-thirds began with severe diarrhea; vomiting was rare. Three times the onset was with angina, twice with pneumonia, and once with measles. Only twice did the paralysis appear without constitutional symptoms. The urine was normal except for once albuminuria and twice indicanuria. The cerebrospinal fluid was always under high tension, clear, alkaline, and containing albumen. There were but few cells, mostly lymphocytes. Three times there was a hypoleucocytosis in the blood, with a mild lymphocytosis. There was frequently a history of other cases of diarrhea in the family. The diagnosis in this stage is very difficult, but in many of the cases there is a definite tenderness over the spine, neck, and legs. The stage of paralysis begins at the time that metastatic inflammatory foci appear in the central nervous system, the virus having been carried through the blood. The first paralysis is usually of the neck, preventing the child from holding up its head, then the muscles of the abdomen and back, and finally the limbs are affected. In the severe fatal cases there is respiratory paralysis. During the initial fever the children perspire profusely. The sensorium is usually clear. Certain cases recover completely, leaving no paralysis. The tendon reflexes are lost, but the skin reflexes remain. There is occasionally an anesthesia. In the eight autopsies there was in each case a mild leptomeningitis. In every case there were extensive changes in the intestines, reddening and swelling of the mucous membrane, especially in the Peyer's patches, and follicles, most marked in the region of the ileocecal valve. Besides this the mesenteric glands were markedly swollen and the spleen was enlarged. The disease is unquestionably an infectious disease, and in certain cases has definitely been carried by a third party. It has distinct locality distributions. No special infecting class of food could be discovered; many cases were breast-fed exclusively. No relation to insects could be found. At the time of the epidemic there was a high mortality among young chickens in the neighborhood, some dying with definite symptoms of paralysis. Hens were not attacked. Some of the chickens when killed showed no pathological changes. This relation to the chickens will be studied further. The treatment during the acute febrile period should consist of calomel and castor oil to eliminate the infecting material from the intestines. The stools should be disinfected, and the cases isolated. The general infection should be attacked with Credé's silver ointment in injunctions. Following lumbar puncture there was often a rapid subsidence of the paralysis. Later electricity, hydrotherapy, and massage are advisable. Passive motions and orthopedic treatment are necessary later.

The Etiology of Acute Epidemic Infantile Paralysis.—Paul Krause and Meinicke studied the autopsies of eight fatal cases of anterior poliomyelitis, as well as blood, lumbar fluid, tonsil scrapings, stools, and urine of living patients. Smears were stained and cultures on many media were made, but nothing suggesting the etiology of the disease was discovered. Many animal experiments were made. Intestinal contents, lumbar fluid, and emulsions of spinal cord were fed and injected into mice, guinea-pigs, chickens, pigeons, and monkeys, without results. Subdural injections of emulsion of the cord of a child into rabbits caused in many cases death with symptoms of cerebrospinal disease and paralysis.

The Treatment by Tuberculosis Immune Blood.—O. Roepke has carried out Spengler's treatment of tuberculosis by injection of immunized blood corpuscles into the blood of the patients in sixty-seven cases, and concludes that the procedure, both for diagnosis and therapeutics, in tuberculous people is equally worthless, and is so absolutely indifferent that physiological salt solutions could be substituted for it with equally good results.

On Tuberculosis Immune Blood.—Weicker and Bandelier carried out Spengler's technique for fifteen months on 200 patients, and conclude that in all the cases treated by them by this method there was no evidence of the favorable action which Spengler claimed for the method.

So-Called Climatic Buboes.—Umberto Gabbi describes a condition of bubo accompanied by fever, without any traces of syphilis, or gonorrhea, which seems to be due in some way to the semi-tropical climate of the countries where it is seen. There are no tuberculous, or skin lesions present. The fever occurs before the inguinal enlargement. The author gives the histories of two cases recently observed, and refers to others related by various other authors. There is little tendency to softening of the bubo; the type of the fever is very irregular; the duration is long, and treatment of little value. There is present a certain amount of lessened resistance due to the hot climate. Only pus cocci were found in the discharge from the bubo seen by the author.—*Rivista Critica di Clinica Medica.*

Book Reviews.

Children in Health and Disease: A Study of Child-life. By David Forsyth, M.D., D.Sc., Physician to the Evelina Hospital for Sick Children; Assistant Physician (Late Physician in Charge of the Children's Department) and Joint Pathologist, Charing Cross Hospital. Philadelphia: P. Blakiston's Son & Co., 1909.

In reading the preface of this book the first impression is that one is bound to be disappointed in the text, as it would seem quite impossible in a book of 350 pages to cover child life in health and disease with even an approach to adequacy, and the perusal of the text is begun in a strong spirit of scepticism. Before many pages have been read, however, this fear is forgotten and a sincere admiration takes its place. The problem before the author was enormous, but he solved it with exceptionally good results. The important facts of the child from intrauterine life to puberty are well covered. The first two chapters are on the physiology of children. Antenatal and natal physiology are succeeded by discussion of growth, digestion, metabolism, feeding, and puberty. As an example of the thoroughness of all this may be mentioned a comprehensive discussion of heat loss and calorie requirements of the infant. The third and fourth chapters discuss the psychological development, and it is rare indeed that one sees so interesting and absorbing an exposition of this fascinating subject. This chapter might well be read by every young mother. School life, its hygiene, medical aspects, and inspection are briefly but well covered. The chapter on training of children deserves special comment. The author shows remarkable insight into the child mind. So far the book has considered the healthy child. It now takes up the child in disease. Mentally defectives and their care are touched upon. General discussion of the sick child and of infant mortality are given, and to round the little book into a complete whole the methods of examining, diagnosis, and treatment of sick children are considered. These are necessarily brief and only such points as are especially applicable to the child are considered. But so far as it goes it is good. The book deserves careful reading from cover to cover by every one who is in any way associated with child life, physician, nurse, or teacher.

Fünfzig Jahre laryngologischer Arbeit auf dem Gebiete der Kehlkopftuberculose, von Dr. R. Imhofer, Prag. Halle a S.: Carl Marhold, 1909.

In this interesting monograph the author discusses the tuberculosis question as affecting the larynx entirely from the historical standpoint, relying almost entirely on continental literature for his extensive study. The bibliography contains 225 references. The work does not purport to be a merely descriptive one, but is, as said, of special value from its historical manner and method, and may well be in the library of every laryngologist. The two most interesting chapters are the first and last respectively. In the former the author discusses the knowledge of the lesions as known to the earlier laryngologists, and in the latter the work of the immediate future as applicable to this special organ. It is a pity that our continental friends so entirely overlook in their contributions the work of the English-speaking races.

Principles of Pharmacy. By Henry V. Arny, Ph.G., Ph.D., Dean and Professor of Pharmacy in the Cleveland School of Pharmacy, Western Reserve University, Cleveland, Ohio. With 246 Original Illustrations. Philadelphia and London: W. B. Saunders Company, 1909.

This new work on Pharmacy consists of seven parts: The first deals with pharmaceutical processes; the second, with the galenical preparations of the pharmacopœia; the third, with inorganic chemistry; the fourth, with organic chemistry; the fifth, with chemical testing; the sixth takes up the prescription, and the seventh contains laboratory exercises. It will be seen that the book is on the same general plan as the standard work of Remington, to which, however, the author makes no reference, not even mentioning that work in his list of books for collateral reading. "The frank intention of this book," as stated in the preface, "is to explain the pharmacopœia from its pharmaceutical standpoint, and if that standard says that a certain chemical is a dextrogyrate ketone, or that a certain drug is a sclerotium, the writer believes that the average student should be able to learn what such terms mean without having to search through a dozen books." Such "intention" is excellent; on the strength of it we looked in the index for "ketone," and on referring to the page indicated found four lines on the subject; we then selected a dextrogyrate ketone, namely camphor, and failed to find an explanation of the term. The references are not always as definite as they might be; for example, "Details in Part V" is somewhat vague, especially as Part V contains more than one hundred pages; if there is any objection to giving the exact page, it would be better to refer to the index at the end of the book. A useful feature of the work is the introduction of paragraphs dealing with the arithmetic of pharmacy and of chemistry.

The Open-air Treatment of Pulmonary Tuberculosis. By F. W. Burton-Fanning, M.D. Cantab., F.R.C.P. Lond., Physician to the Norfolk and Norwich Hospital, Honorary Visiting Physician to the Kellogg Open-Air Sanatorium. Second Edition. New York: Paul B. Hoeber, 1909.

The author of this little book is most enthusiastic about the open-air treatment when combined with all the minute details that accompany it. He acknowledges the incompleteness of his title but in the text we find fresh air by no means the only part of his system. He deals especially with the significance of fever and accelerated pulse rate, and points out where rest should end and exercise begin. The infinite care with which he states these details and the insistence with which each command is ordered to be followed up by the one in authority are praiseworthy points; for eternal vigilance during and after the "cure" alone will make a good showing in the treatment of real pulmonary tuberculosis; that is, real clinical cases where the suspicion of the disease has not grown to the size of a confirmed diagnosis on insufficient evidence such as the recent tuberculin tests so often considered as final proof. The questions of diet and after-treatment are well considered. The final chapter gives the requisites for the open-air treatment accompanied by some illustrations of shelters such as are of practical use. The author takes up the opsonic theory of Wright and some of the more recent methods of diagnosis, but otherwise his book is eminently practical, sensible, and sound.

A Text-Book of Physiological Chemistry for Students of Medicine. By John H. Long, M.S., Sc.D., Professor of Chemistry in Northwestern University Medical School. Second edition, revised; with 42 illustrations. Philadelphia: P. Blakiston's Son & Co., 1909.

This volume on Physiological Chemistry forms a useful companion to the author's other works, namely, General Chemistry, and Analytical Chemistry, both of which have been noticed in these columns. The author has succeeded in keeping the present volume within very reasonable limits; yet it covers the ground usually gone over in the medical schools. In this revision some important changes have been made: the new protein classification of the American societies has been adopted; a much fuller discussion has been given to the subject of the urine, and a new chapter has been added on the methods of urine analysis. As the work is intended for beginners, references to the literature are not given.

Dorland's American Illustrated Medical Dictionary. A new and complete dictionary of terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, Nursing, and kindred branches; with new and elaborate tables and many handsome illustrations. Fifth Revised Edition. By W. A. Newman Dorland, M.D. Philadelphia and London: W. B. Saunders Company, 1909.

It is really unnecessary to do more than chronicle the appearance of a new edition of this well-known dictionary. The work does not differ from the fourth edition except in the additions which the constant advance in medicine and the allied sciences renders necessary. There are forty more pages in this edition than in the last, but owing to the use of thinner paper the book itself is no thicker. The faults that have characterized the former editions are present in this, especially the very annoying one of defining by synonyms and not explaining. For example, one wants to know what is Magendie's foramen: he looks under *Magendie* and is referred to *foramen;* under *foramen* he looks for Magendie's f., and finds the definition: "Same as Arachnoid f."; he turns back to *Arachnoid* and finds no mention of it, then he goes again to *foramen* and looks for Arachnoid f., which is defined: "the foramen of Magendie." The claim made in the preface that the BNA anatomical terminology has been included is not substantiated by a search for the new BNA terms; some are there and some are not. However, with all its faults, and they are many, this is the best, because the most recent, of the medical dictionaries.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Thirty-seventh Annual Meeting, Held at Richmond, Va., October 19, 20, and 22, 1909.

THE PRESIDENT, DR. GARDNER T. SWARTS, PROVIDENCE, R. I., IN THE CHAIR.

The Second Decennial Revision of International Classification of Causes of Death.—Dr. CRESSY L. WILBUR of Washington, D. C., stated that the second decennial revision was the most important event that had occurred affecting vital statistics during the past year, and the possibility of twenty-three nations joining in this revision reflected much credit upon the American Public Health Association, which recommended at its Ottawa meeting, in 1898, the Bertillon classification. While the second revision was not radically different from the first, we were at the beginning of a great undertaking, namely, the preparation of a national nomenclature of diseases and causes of death, conducted by a committee of the American Public Health Association. The international classification was somewhat elastic, so that the titles of the tabular list could be subdivided readily to meet special requirements. The section on vital statistics appeared to be ready to approve certain changes in the present standard certificate of death with reference to obtaining better information as to the cause of the death and the occupation of decedent. He believed that the most important practical measure which could come up for consideration next year would be the preparation of a series of uniform statistical tables relating to births, still-births, deaths, sickness, marriages, and divorces for use in the federal, state, and municipal reports and bulletins. He proposed to the officers of the association and also members of the councils of the section on vital statistics that they cooperate by the appointment of special committees, whose work could be aided by the Census Bureau in the preparation of uniform tables to be used in registration reports. Great progress had been made in the last few years in the registration area, yet so far, with the exception of North Carolina, there was no registration state in the South.

Dr. H. W. HILL of Minneapolis asked Dr. Wilbur how he attempted to phrase that part of the death certificate which asked for the cause of death.

Dr. M. L. PRICE of Baltimore asked what numbers in the International Classification of Deaths were changed in the last decennial revision; what the present numbers were, and what they were intended to mean in their classifications.

Dr. WILBUR, in closing the discussion, said that there was a joint meeting of the committee on form and council of vital statistics section, and a complete agreement was had as to the form of questions for the cause of death. The note printed on the face of the blank was as follows: "State the disease causing death, or in deaths from violent causes, state, first, the means of injury; second, whether accidental, suicidal, or homicidal." In answer to Dr. Price's question, he had received a communication stating that Census Bulletin No. 104 had been printed and two copies had been sent to him. This contained the title of the classification, and each title which had not been changed or modified from the former series was noted by an asterisk. Dr. Price could see what changes had been made.

The Management of Milk-Borne Outbreaks of Typhoid Fever.—Dr. C. V. CHAPIN of Providence, R. I., referred to an outbreak of typhoid fever among the customers of a certain dairy in Providence. The only evidence that the milk supply was the cause of typhoid fever was in the excess of patients among the persons supplied. Out of 600 dealers in Providence, 155 had had one or more cases of typhoid fever during the last four years. In a study of sixteen outbreaks the distribution of the cases in point of time suggested that the infection was not continuous, but depended on a single distribution of the milk. As shown by Davies, Craig, and others, carriers caused infection only in an irregular and intermittent manner. The occurrence of two or three cases in a route of from 100 to 1,000 families within a week required careful investigation. When the milk supply was found to be defective, and the source not determined, it should be shut off or pasteurized, and when typhoid was found among those who handled the milk the patient should be removed from all contact with it. Precautionary measures should be carried out for three or four months from the beginning of the last case.

The Utility of the Domiciliary Visit in the Struggle Against Yellow Fever.—Dr. CARLOS MANUEL GARCIA of Mexico stated that the slight epidemic of yellow fever which suddenly broke out at the end of May last year in the Port of Leguana del Carmen furnished an opportunity to say a few words about the utility of the domiciliary visit, that is to say, the isolation of confirmed or even suspected cases, the detruction of the larvae and the infected mosquitos. This constituted the most practical application of the immortal discovery of Dr. Finlay. These cases had given rise to the doctrine that in those places in which yellow fever was endemic, it was maintained by the children under 10 years of age, who were natives of the locality. It was supposed that these children were attacked by very mild forms of the disease and were susceptible of propagating it by means of the mosquito. They had not obtained experimental sanction of this doctrine, but we could understand the absolute necessity of isolating at the earliest possible moment every nonimmune, among whom he would include children under ten years of age who presented any of the initial symptoms. This practice led to the successful termination of the epidemic in Leguana del Carmen.

The Campaign Against Yellow Fever on the Isthmus of Tehauntepec.—Dr. FRANCISCO VALENZUELA of Mexico stated the importance of the international traffic across the Isthmus had brought to that territory a great number of nonimmunes, which had led to a great increase in the number of victims. The campaign, according to the doctrines of Finlay, was organized under Dr. Garcia at the city of Tehauntepec in May, 1904, and subsequently extended to the whole of the Isthmus. The excellent results obtained were a matter of congratulation to all. The passenger traffic was under the charge of sanitary agents on board the cars of the Tehauntepec Railway. When a passenger was found to be sick the agent investigated the case, taking into consideration the sanitary condition of the country from which the sick persons came. A report was forwarded to the sick man's destination, as well as given to the agent on the train with which the passenger desired to connect. This traveling agent collected all the news possible, thus it enabled the chief of the service to receive daily and timely reports of all cases of an alarming character. Isolation of the sick, destruction of the mosquitos by fumigation, and the covering of ponds and swamps with oil to destroy the larvæ were the three principal factors in suppressing yellow fever.

Dr. WALTER WYMAN of Washington, D. C., said that when we think that only a few years ago Vera Cruz was one of the worst infected ports of the Western continent, that it was a constant menace to the United States, but now it was free from that infection and that through the scientific and sanitary efforts of the Mexican Government, represented by Dr. Liceaga and backed by President Diaz, he thought it was a remarkable tribute to the intelligence and energy of our southern neighbors. Not only had they eliminated yellow fever from the Mexican Republic, but

the forces which they were now using were turned against malaria and they expected to eliminate malaria from Mexico. It looked very much as though they had conquered in the Western Hemisphere the disease called yellow fever.

Dr. Peter H. Bryce of Ottawa, Ontario, said that we could not only congratulate ourselves in the northern States for the fight which was being waged against typhoid fever, but also because of the magnificent task that Dr. Liceaga and his board had taken in hand and accomplished in stamping out disease. It made no difference whether it was typhoid fever, smallpox, yellow fever, or tuberculosis which we were all fighting against to-day. He could not withhold his tribute to the splendid example set by Dr. Licéaga and the Board of Health of Mexico City.

Dr. Frederick Torralbas of Havana, Cuba, said that Havana was to-day in such a condition that they could control entirely the history of any case of yellow fever which might become developed from its very beginning. For this purpose they had this year sixty district inspectors who were in charge, visiting each house in Havana and making an average of 20,000 houses every ten days, which would cover the whole town a little less than three times during the month.

Scope and Value of Lectures.—Dr. Herbert D. Pease of New York City said our form of government placed the responsibility of government upon the citizens as a whole. Never in our history had the public been more alive to the details of administration than at present. Everywhere we found this reaching out on the part of the populace for a more direct remedy. Truth generally made for simplicity, ignorance for complexity. In his opinion, we might say that the cardinal principles in education work in hygiene were as follows: A simpler statement of the known, the unknown, and the debatable. The manner and method of expression must be secondary, and they were, nevertheless, of vital importance for success. The speaker must insist upon getting the audience and then he must hold it or he was inefficient. Without money the task was greater, but was by no means hopeless. In the pioneer work against tuberculosis those who had the least money made greatest progress because lack of means necessitated more volunteers. To be assured of an audience one must advertise and continue to advertise by special letters, handbills, and multiple letters, and even newspaper advertisements. In advertising, the subject of a lecture should at all times receive the greatest emphasis, then follow with the names of the speakers, allowing the time and place to come after this. Every epidemic should be used as an opening gun in the campaign against that particular disease. The larger advertisements should be put on first and later be followed with the cards, multiple letters, etc. First presented in the lecture were the problems already solved, next those not entirely solved, and third topics about which there was controversy. Pictures or lantern slides should be used in effective lectures on certain subjects. These slides might be interspersed with moving-picture slides, which added a certain amount of interest to the program.

Teaching Hygiene in Elementary Schools.—Miss Isabelle F. Hyam of Dorchester, Mass., stated that the State had taken upon itself to educate the children, and it seemed reasonable that as much attention should be given to the child's body as to its mind. Children could rarely change their own environment, but in many ways they could control their lives in an effort at better living if they were properly prepared. The schoolhouse and schoolroom should be examples of cleanliness, and afford every means to help the child to live. It seemed hopeless to teach hygiene when the child had but to look about and see filth. The child was the center of his little world, and was more closely concerned with the home. The facts in the home were care of the home, furniture, food and its preparation, hygienic clothing, and personal hygiene. The first lesson in ventilation was that there must be an outlet for the foul air at the top of the room, which could be illustrated and emphasized in a cardboard or block house. Scientific impersonation played a large part in the education of the child. For some children who were physically unfit, only the open air school was proper. They learned to love the open air, and the benefits of such a school were obvious. Health was fundamental, and in the school the child should be trained in habits of health. In order to accomplish this end conditions in the schoolroom must be wholesome. The school should be well lighted and the air fresh. There should be time for play out of doors and facilities for bathing.

School Instruction in Hygiene and Sanitation.—Dr. John W. Richie of Williamsburg, Va., stated he would refer only briefly to hygiene, limiting the scope of his remarks to the public school, between the fifth grade and the high school. The teaching of sanitation had proved a great success because it was made so simple that it could be taught to pupils below the high school age. They forced the pupil to examine everything and state the conclusions to be drawn from the evidence, and when the pupil accepted as facts what his own reason told him was true, that was called the open-mindedness of youth. Much good could be done by teaching the facts as to a few specific diseases. Pupils needed to be taught about the microscope, plants, and animals that grew in the body and caused disease. They needed to be taught something of the defense of the body against germs in order that it might not seem a monstrous thing to put matter from a cow into the human body. They must be made to understand that food and fresh air were more important than patent medicine. His whole experience had been that it was a perfectly simple matter to give the theoretical background to children, and he who would shorten the subject by omitting the simple remedy was in danger of breaking the circuit altogether. Everywhere we found intelligent people who believed in sanitation, but even among these people ignorance of the simplest principles of bacteria was really disgusting. They seemed to have no idea of what a real disease germ was, but burdened themselves with useless precautions. For instance, they filtered the water from the roof to free it of typhoid fever germs, overlooking entirely the closet in the back yard. The subject of sanitation should be allowed sufficient time to give pupils some understanding of the subject, and the pupils should be liberally supplied with printed matter for study. Bulletins should be sent to the teachers as well as the pupils. This teaching had a decided effect in educating the parents as well as the children. The public drinking cup disappeared quickly where sanitation was taught. The old hygiene was not practicable, but the new hygiene was practicable, and we should see to it that in teaching hygiene the conditions should be hygienic in the schoolroom.

The Way to Study Hygiene in the Normal Schools.—Dr. Adrian De Garay of Mexico City stated that the difficulty in this matter had always been as to the manner and form in which such knowledge is promulgated. It was very necessary to give the very best instruction to all the world, but above all in the primary schools. It was in a condition of health that the citizen became of value to the country. There should be two courses of hygiene, one general and the other special hygiene, each taught with thoroughness. In hygiene, as well as in other studies, we should try to make it as practical and interesting as possible. Practical instruction could be given in three ways: by means of the chemical and bacteriological laboratory, by means of excursions and study in such places as theaters, water supply houses, public buildings, and so on, and by means of hygienic amusements. Hygiene should be one of the principal subjects taught in normal schools; it should be studied during the last part of the term; instruction

should be given in an entirely practical and agreeable manner, laboratories established, and hygienic trips organized.

Instruction in Personal and Public Hygiene in the Medical College.—Dr. F. F. Wesbrook of Minneapolis stated that those in public health work were hard on the doctor, although they realized his difficulties, and they recognized that he had perhaps been the leading spirit in all of the advances of hygiene. He was a teacher, and not a practitioner, yet he wished to pay his tribute of respect to the medical profession. The medical profession, through the American Medical Association, was doing its best to raise the standard of the profession by seeing that none may enter who were not well prepared. It was the desire to prepare the medical man to regulate matters, in conjunction with other forces with which he would come in contact, very much more than he had done in the past. While they did not expect to make them all medical hygienists, they did expect to prepare them to work with such forces as they had represented there.

Results of Federal Control of Viruses, Serums, Toxins, and Analogous Products.—Dr. John F. Anderson of Washington, D. C., stated that the results of Federal control have been (1) that manufacturers had been required to put their barns, stables, and laboratories into sanitary condition. (2) Complete separation of tetanous and tuberculosis work from the work of producing diphtheria antitoxin. (3) All establishments were required to be equipped with proper laboratory facilities. (4) Each lot of virus was required to be examined bacteriologically, and a special test made for tetanous bacilli, and detailed records kept of such examination. (5) The sale of the old-style "dry" lymph points was no longer allowed. (6) All animals used for propagation of vaccine virus were required to be autopsied, and if the animal had been suffering from an incurable disease the virus was not allowed to be sold. (7) All sera were required to be examined where standards had been established for toxic contamination, and correctly labeled, and to state the date beyond which they could not be expected to yield their specific effects, and to contain no excessive amount of preservatives. (8) Standards for diphtheria and tetanous antitoxins had been established.

How an Enlarged and Uniform National Health Administration May Be Secured.—Dr. Joseph Y. Porter of Florida stated that the phantom of offended dignity had often arisen in the past to arouse suspicion of improper interference when the Federal Government had through Interstate Commerce stopped to interpose authority, even in an advisory manner in the management of public health matters. It was apparent that this was true to-day, particularly in Massachusetts, Ohio, and Illinois in reference to sanitary matters, and the control of disease producing conditions within their confines. By advocating an enlargement of the powers of the general government in health control throughout the country which should be uniform and impartially administered in all sections of the country, excepting none, it was not herein desired that the arguments advanced or the opinions expressed should be understood as recommending or advising that the health police powers of a state should be abridged or superseded by the general government, but rather that some of the difficulties in the present system of administration might be remedied and the awkwardness of many existing conditions corrected.

Tuberculosis from a Maritime Prophylactic Point of View.—Dr. Antonio Matienzo of Mexico City stated that it had been demonstrated that tuberculosis was a social danger, and that it found at sea excellent conditions for the breeding of the germ which propagated it. He proposed that an office for medical inspection be established in the principal ports under the control of the sanitary authorities, fully authorized to examine every passenger; to require the great steamship companies to establish in all their ships a special department with berths for tuberculous children. The infection of the air having been proven, this is all which should occupy the attention of the hygienist. All people should be prevented from expectorating on the floor and in the berths, and for all tuberculous passengers there should be placed some concise precepts in the room relating to the danger of expectoration to the patient himself as well as to everybody else.

What May Be Done to Improve the Hygiene of the City Dweller.—Dr. S. A. Knopf of New York read this paper (to be published later).

Prophylaxis in Exanthematic Typhus.—Dr. Genaro Escalona of Mexico stated that in the central tableland of the Mexican Republic this disease assumed an endemic form. The mortality reached a very high figure. The physicians of Mexico agreed that Mexican typhus presented certain characteristics that were different from the European type. The disease did not have a sudden development. There was a period of ascension and descension through irregular manifestations. Three important points might be considered: (a) The sanitation of the town; (b) the disinfection of the premises occupied by the patient; (c) the disposal of articles coming in contact with the patient. The patient should be isolated and his bed clothing disinfected by means of boiling or destroyed by fire. All the toilet utensils should be well disinfected and the excreta should be carried off through the drain by an abundant amount of water. The skin should be bathed and the hair cut, as well as the mucous membrane disinfected.

Some Consideration Relative to the Tansmission of Syphilis by Vaccine.—Dr. Francisco de Bernaldez of Mexico stated that the Jenner or arm-to-arm vaccination against smallpox had been discredited by almost all nations because of the possibility of syphilitic inoculation. They were now well aware that in order that this might take place it was necessary to have well-studied conditions, but much care must be used in collecting the lymph. From observations already made, it was stated that the lymph must be taken from persons over three years of age, that being the age at which hereditary syphilis made itself apparent. The vaccine pustules must be of seven days' growth because the contagious infiltrations had a longer period of incubation. The transmission of syphilis through the agency of humanized vaccine could easily be avoided if we knew the conditions under which such transmission was possible. The Jennerian vaccine was recommended because it conferred a greater degree of and a more lasting immunity.

Report on Yellow Fever in the Mexican Republic from August 25, 1908, to Date.—Dr. Eduardo Licéaga of Mexico stated that this was his sixteenth annual report as to the general conditions of Mexico regarding the presence of yellow fever. The paper was accompanied by diagrams, and he referred to the number of isolated cases in different parts of the country, mentioning a current supposition in Cuba to the effect that native children contracted yellow fever in a mild form and infected mosquitos which thereby gave rise to isolated cases of yellow fever. The covering with oil of standing water, filling up holes, fumigation of dwelling houses and surveillance of railway passengers constituted some of the means at present employed in fighting this disease. In the ports of Coatzacoalcos, on the Gulf Coast and Salina Cruz on the Pacific it was nearly four years since a single case of yellow fever had been observed.

The Necessity of Isolated Syphilitic Prostitutes to Prevent the Propagation of the Disease.—Dr. Joaquin Huici of Mexico said the prophylaxis of syphilis was a most serious and interesting question, and had given rise

to a division among scientific men. The disease had caused more ravages in the human race than any other transmissible disease, not only rendering the individual useless for work, but endangering those with whom he came in contact. A uniform set of regulations to control prostitutes should be adopted. Governments were under obligation to enact provisions tending to prevent the transmission of disease, and syphilis and gonorrhea, being continually transmitted, should be included in that obligation, as public women were the principal sources of those diseases and they were the ones to whom such provisions should be applied.

Some Sufficient Means of Checking Syphilitic and Gonorrheal Contamination.—Dr. JUAN BRENA of Zacatecas, Mexico, said the efforts of an association like this would be fruitless without the cooperation of the social classes. In the effort for the extermination of leprosy and tuberculosis the people joined spontaneously, but the same was not true with reference to venereal disease. Fortunately the conviction had grown as to the practical utility resulting from giving universal publicity to clear rules establishing the conditions which rendered immune communications between the healthy and venereal subjects. Pupils in school were taught the evils resulting from the use of tobacco and alcohol, and it would be a meritorious work to instruct the older pupils as to the deadly action of impure pleasures. Literature should be distributed explaining the gravity of these diseases, and means of prevention. Municipal doctors and others appointed for the purpose should attend these patients free of charge and lectures on the subject be provided for. Inexperience was the cause of great harm to the young, and let us not fear to help them over the thorny road.

The Scope of Public Hygiene in the Betterment of the Home Life in Towns and Cities.—Mr. ROBERT W. BRUERE of New York stated that everyone seemed to take it for granted not only that disease was curable, but that it was the business of the medical profession to cure it or prevent it. It had been many years since the medical profession was regarded as a dispenser of medicine, and not as a preventer of disease, more particularly social disease. Last year there were 10,147 deaths from tuberculosis in New York, and about the same number the year before. The death rate from other diseases had greatly decreased during the past seven years in New York, but this had not been the case with tuberculosis. Last year our association had charge of 4,000 infants, and everything was done that was possible by simple education and the teaching of hygiene to reduce mortality. The great difficulty we encountered was that the mothers were not able to purchase the food that those children required. Ten per cent. of them were forced to earn wages away from home, and over 73 per cent. of the mothers belonged to families where the income was less than $15 a week, some three and four hundred dollars less than the Committee on Standard of Living maintained was necessary for the average family. The medical profession had done much to teach the world that disease could be successfully prevented only when it was attacked by an organized community, but he believed that we could not cut the death rate below ten per cent. until we attacked the problem of the poverty of the worker.

The Scope of Public Health Work in the Prevention of Dependency.—Mr. HOMER FOLKS of New York said that the public health work included both the education of the individual and the community, and if the work could be carried on comprehensively, efficiently, and adequately the number of dependents would be greatly reduced. Ill health was a very prolific cause of poverty, whether due to individual or social causes. The first strong movement in New York for the prevention of tuberculosis was organized by a society concerned with the relief of the poor. Much remained to be done in the prevention of typhoid fever, while diphtheria, whooping-cough, and scarlet fever were gradually being brought under control. We should not make prominent headway against alcoholism until we had the support of public health authorities. The movement for the prevention of venereal diseases, from which the public health authorities could not much longer hold aloof, must ultimately result in a great lessening of the demand upon our hospitals, institutions for children, institutions for the blind, and insane asylums.

The Sanitary Requirements of Ventilation.—Dr. W. A. EVANS of Chicago said that good air was the most important problem before the Health Department. Ten thousand deaths a year from bad meat, bad water, or bad milk would produce a world-wide scandal, yet we accepted 10,000 deaths from bad air with complacency. The following were the basic principles of ventilation: 1. Attention must be concentrated on the habitual zones of a room, meaning a space from four feet above the floor to six and a half feet above. 2. Dead zones and corner eddies must be encouraged as settling places for bacteria. Such spaces must be cleaned daily with moist methods. 3. The breathing zone must be occupied by an even-up current of air, moving at the rate of at least sixty feet a minute from multiple floor inlets to multiple floor outlets. The temperature of the air reaching the breathing zone should never be higher than 80° F. and was better if it was under 70°. 4. The ventilating air should never enter the room at more than 40° below body temperature. 5. Air ducts must be short. 6. No particular attention should be paid to humidity. 7. The volume of air per quiet person per hour should be five hundred feet. 8. Under no circumstances should the windows be fixed, but a gale of wind should be allowed to blow through each twenty-four hours.

The Ventilation of Industrial Establishments.—Dr. C. T. GRAHAM ROGERS of New York stated that the Department of Labor of the State of New York had done much toward the betterment of public health in that State, besides which the Commissioner of Labor had sent a representative of the department to participate in this meeting. Some 430 separate air tests were made during six months of the fiscal year 1908, and a complete tabulation of the results might be found in the Eighth Annual Report of the Commissioner of Labor. Great strides had been made in improving the ventilation of schools and dwellings, but comparatively little progress had been made with the factories. It was to be hoped that some means would be secured to impress the laity with the importance of the subject. Inspections had been made of the New York bakeries, potteries, polishing and buffing rooms, tailor shops, cigar factories, clothing shops, jewelry stores, department stores, and others. The cry in the past had been for more light, but now it was for more air. We needed both, increasing the resistance of the body to disease, and making the nation stronger physically, mentally, and morally.

Cooperative Efforts in Supervision and Control of Milk Supply.—Dr. F. D. BELL of New York said the Board of Health of New York City required a permit from every milk dealer in the city, and if the dealer did not conduct his business in accordance with the requirements he was brought into court. The average milk dealer knew little about chemistry or bacteriology of milk, and an absolutely sterile milk was almost impossible to obtain because the public was not sufficiently educated to exact this quality of milk. The public was unwilling to pay for such a grade of milk, and the dealer and the average producer were not of a type capable of producing this quality. The average dairy farm was too small to produce milk economically and the dealers were unable to afford any systematic laboratory supervision or proper building and apparatus which they had come to believe were necessary for the production of milk. Regulations had been promulgated with the

health authorities, which, if rigidly enforced, would mean that the towns would be without any milk supply at all. The dealer and health officer should consider themselves friends, and such a feeling could be brought about only by the gradual process of developing mutual confidence.

An Investigation of the Extent of the Bacterial Pollution of the Atmosphere by Mouth Spray.—Mr. C. E. A. Winslow of Brookline, Mass., said that with the progress of exact knowledge sanatoria had been led to place less and less emphasis upon the part played by the atmosphere in the spread of zymotic disease. It had been shown that quietly inspired air was germ free and most of the particles in the mouth spray were rather coarse and settled rapidly. It was not intended to minimize the real danger from mouth spray, as large numbers of bacilli were discharged in coughing by some consumptive patients. Ziesche found in one case 20,000 tubercle bacilli on a glass plate of fifty square inches in area when exposed for half an hour at sixteen to thirty-two inches in front of the mouth of a tuberculous patient. In work rooms, offices, and such places the space between the heads of the workers should be at least three feet. This furnishes no basis for a belief that tuberculosis or any other disease was contracted to an appreciable extent through the inspired air, as the spray quickly settled and the conviction was not generally gaining ground that aerial infection of any sort was a minor factor in the spread of zymotic disease.

The Sex Problems in Industrial Hygiene.—Mrs. Florence Kelley of New York stated that it was more than one hundred years since the working people of England first began in the name of public health to get a shorter day for women. In 1847 a bill was passed in England limiting woman's labor to ten hours, but in 1895 in the enlightened state of Illinois, the Supreme Court held that it was unconstitutional to grant to women the same degree of protection. In the majority of our states it was lawful to require women to work in a factory or laundry or store any number of hours that a rush order might require. Our legal procedure was very curious. The Supreme Court was presumed to know only those items of common knowledge specifically laid before it, and it was necessary to collect some one hundred and sixty-two pages of common knowledge. For some time there was a law in New York that girls should not work in the stores after ten o'clock, but it was not enforced because of the claim that there were more important matters to look after. About twelve years ago the miners of Utah secured an eight-hour day because they worked underground, but the bakers of New York, who also worked underground, failed in their efforts.

The Relation of Life Insurance to Public Hygiene.—Dr. Lee Frankal of the Metropolitan Life Insurance Co. read this paper in which he contended that in no other country in the world would it be necessary to explain the relation of insurance to industrial and social hygiene. In Europe insurance was compulsory, and in the larger European cities the great mass of citizens were insured along the line of prevention. Their company distributed four million pamphlets, entitled, "The War on Consumption," calling attention to the fact that there were places where the individual might obtain treatment. They desired to cooperate with any agency in the community towards the prevention of tuberculosis and other preventable diseases. In Chicago they were asked to distribute copies of the ballot, which enabled them to secure a municipal sanatorium. They were now making experiments of sending a nurse to every sick policy holder, which had been successful so far. Their policy holders were being visited weekly, and if desired this association might make use of their organization in the promotion of public health.

Scope and Value of the Daily Press and Press Bureaus.—Dr. John V. Kingsbury of New York stated that the scope of publicity in public health was as broad as the scope of publicity in politics, and in order to be effective it must be made as striking as it was possible to make it. It was our problem in public health to arouse slumbering humanity to a full realization of the meaning of the frightful fact that disease germs caused the death of over fifty per cent. of the human race, and that in addition to this suffering and poverty which could hardly be imagined, they must convince the public that this great sacrifice was almost wholly needless. It was only within the last few years that there had been any considerable demand for the knowledge given the world almost a quarter of a century ago by Koch. They must learn from the patent medicine man his secrets of publicity. The trouble thus far was that all the money that had been given in this field of work had been put into the manufactory department and the advertising end of the business had been almost entirely neglected. They must get their goods into circulation. Moreover, there was a lack of proper cooperation between the producing and developing departments of their work. The American Public Health Association had long been in the business of producing knowledge of inestimable value. If advertisements could create new wants and new desires the satisfaction of which built up business for others, surely practical publicity could create a demand for such knowledge, and the nature and scope of such work would be limited only by its ability to get results.

The Physiological Aspects of Ventilation.—Dr. Theodore Hough of the University of Virginia said there was no argument against the hygienic importance of ventilation. The history of the subject showed that it was not so simple as often supposed. The poisonous material in the air of the room did not come from the lungs, but from the skin, clothing, decaying food particles in the mouth, or catarrhal exudates from the air passage. It was important to distinguish between the acute effects which were produced by prolonged exposure. The toxic material, so far as it was a factor, did harm chiefly when it acted over a comparatively long period, and they must seek elsewhere the explanation of the acute effect. While the introduction of fresh air was of great importance in removing the unfavorable physiological factors, it was even of more importance to maintain an even temperature of 68° to 70° since at that temperature the humidity was almost negligible, while the other ill effects, especially on the nervous system, seemed to be less noticeable and less important.

Age Problems in Industrial Hygiene.—Dr. Owen R. Lovejoy of New York said that in many States they were embarrassed by the attempt to secure the enactment, and after that the administration of laws regulating the ages at which children should be employed, because of the fact that it was impossible to tell when the ages began. The relation of age to industrial employment needed no discussion, yet they constantly met ignorant people who thought that a child was a small man, and that burdens which were proper for the man were proper for the child, if measured according to the child's age. There was a period between ten and sixteen that was so revolutionary in its nature as scarcely to be exceeded by the needs of the infant. It might be safely predicted that the awakening to the dangers of typhoid and other diseases would in another decade make the health department one of the most important, if not the most important department in any of our city governments. It had been assumed that the best employment for the child was agricultural, but it had been shown recently that on many truck farms conditions prevailed that were seriously detrimental to the child. Health officers should study carefully the relation of the industrial education of the community to the development of the physical life of the child.

Resolutions.—The following resolutions were introduced and adopted:

Resolved, That the American Public Health Association appoint a conference committee of five members to meet with the conference committee of the American Medical Association and with the conference committee from the Conference of State and Provincial Boards of Health with a view to considering the matter of cooperative work in public health with instructions to report at the next meeting of the American Public Health Association.

Resolved, That a committee of seven be authorized to arrange, if feasible, for the maintenance by the Association at the Fifteenth International Congress of Hygiene and Demography to be held in Washington in 1910, of headquarters, an exhibit, participation in meeting, official recognition, and such other matters as the committee deems proper.

Officers.—The following officers were elected: *President,* Dr. Charles O. Probst, Columbus, Ohio; *Vice-Presidents,* Dr. Charles A. Hodgetts, Toronto, Ont., Dr. Ernst C. Levy, Richmond, Va., Frederico Torralbas, Havana, Cuba; *Secretary,* Dr. William C. Woodward, Washington, D. C.; *Treasurer,* Dr. Frank W. Wright, New Haven, Conn.; *Executive Committee,* Drs. Eugene Buehler, Indianapolis, Marshall L. Price and Cressy L. Wilbur, Washington, D. C.

It was decided to hold the next annual meeting in Milwaukee.

Philadelphia County Medical Society.

At a stated meeting held October 27 Dr. T. Turner Thomas read a paper entitled "Capsulorrhaphy for Recurrent Dislocation of the Shoulder." He presented three patients on whom this operation had been performed successfully and he reported a fourth in addition. In three there was almost perfect restoration of function, while in the fourth, in which an earlier operation had been undertaken but without success, there was some tardiness in the final result on account of infection from a ligature and close approximation of the rent in the capsule. Dr. Stricker Coles read a paper entitled "The Frequency and Prevention of Puerperal Sepsis." He cited the infrequency of the complication under existing conditions, especially in private practice, and even when the surrounding conditions were bad. This result had been secured through asepsis and infrequency of examination during labor. Dr. J. J. Gilbride read a paper entitled "Starchy Food as a Factor in Some Cases of Dyspepsia." He referred to the fact that some persons are unable to take such articles of food as bread and potatoes without suffering epigastric distress and other related symptoms. Tincture of nux vomica before meals is a useful therapeutic agent in this connection. Dr. Oscar H. Allis read "A Memorial Sketch of the Late Dr. Richard J. Levis."

Maxillary Sinusitis and Osteitis.—E. J. Moure and Brindel emphasize the fact that osteitis often accompanies chronic suppurations of the maxillary sinus, and is found to be a benign complication. There is much importance attached to the diagnosis of the cause of the suppuration and the pathological conditions found in the bone. In many cases this osteitis is the result of a general infection by syphilis, often many years previous to the suppuration, and of which there has been no previous diagnosis. In some of these cases the syphilis was hereditary. In such cases antisyphilitic treatment brings about a rapid cure of the condition. In these syphilitic cases the bone is found to be spongy and bleed easily and profusely, so that the operation may have to be stopped to control the hemorrhage. In other nonsyphilitic cases there is an edematous and degenerated condition of the antral lining, with polypi, periostitis, and necrosis of the bone. The treatment, aside from general measures, demands a wide opening of the antrum into the nasal fossa, so as to keep up efficient drainage.—*Journal de Médecine de Bordeaux.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

North Carolina Board of Medical Examiners.

June, 1909.

ANATOMY.

Answer only ten questions.

1. Name the bones of the head and describe the frontal bone.
2. Where does abdominal aorta commence and where does it terminate? Name its branches.
3. Name the principal lobes of the brain and the fissures dividing them.
4. Give the origin and function of the trigeminus (fifth cranial) nerve, and name the divisions of the same.
5. With what bones does the astragalus articulate?
6. Describe the stomach, give its average size, attachments, regional location, gross structure, blood and nerve supply.
7. Give origin, insertion, and action and nerve supply of the following muscles: deltoid, soleus, and quadratus lumborum.
8. Give the surgical anatomy of femoral hernia.
9. Locate and describe the ovaries.
10. Give a histological description of an artery.
11. Describe the rectum.
12. Describe the iris, give its blood and nerve supply.

PHYSIOLOGY AND HYGIENE.

1. What evidence is there that the secretion of urine is not a simple process of filtration from the blood? State the probable nature of the stimulation controlling the secretion of urine.
2. Explain the structure and use of each of the three coats of blood vessels.
3. Name the principal centers of organic function situated in the medulla oblongata.
4. Give the teachings as to the (*a*) origin, (*b*) functions, (*c*) variations in number of leucocytes.
5. Define the functions of carbohydrate foods.
6. Discuss enzymes, giving (*a*) their general character, (*b*) six principal ones, where chiefly found, and their respective actions in the process of digestion.
7. What is the significance of (*a*) nitrates and (*b*) nitrites found in drinking water?
8. Give the prophylaxis of uncinariasis.
9. Discuss municipal supervision of a city's milk supply.
10. Discuss the contamination of air in dwellings consequent upon improper lighting, heating, and ventilation.

MATERIA MEDICA.

1. Name the organs influenced by (*a*) a cholagogue, (*b*) a sialogogue, (*c*) an oxytoxic, (*d*) a diaphoretic, (*e*) a mydriatic.
2. Give the official name, using the correct Latin terminations, of (*a*) Epsom salts, (*b*) Dover's powder, (*c*) calomel, (*d*) salol, (*e*) Fowler's solution, (*f*) Hoffman's anodyne, (*g*) cod liver oil, (*h*) sulphonal, (*i*) aristol, (*j*) spirit of nitroglycerin.
3. Define a tincture. Name four of the most important official tinctures and state per cent. strength of each.
4. Give the dose of (*a*) apomorphinæ hydrochloridum, (*b*) arseni trioxidum, (*c*) chloralum hydratum, (*d*) atropinæ sulphas, (*e*) hydrargyri chloridum corrosivum, (*f*) strychninæ sulphas, (*g*) hexamethylenamine, (*h*) tinctura aconiti, (*i*) tinctura gelsemii, (*j*) glandula suprarenalis sicca.
5. Give specific treatment for diphtheria and state (very briefly) how the remedy is obtained.
6. Give specific remedy for myxedema.
7. Write a prescription for dysentery.
8. Name four drugs which might be useful as local applications in tonsillitis (official remedies only).
9. Name five agents (not official drugs) which frequently cause poisoning.
10. Give specific antidote for poisoning by (*a*) bichloride of mercury, (*b*) arsenic, (*c*) iodine, (*d*) opium (emetics, stomach pump, etc., being taken for granted).

CHEMISTRY AND DISEASES OF CHILDREN.

1. A patient is found with a temperature of 104° Fahrenheit. Express this in Centigrade. (*b*) Express the equivalent of one grain (decimally) in grams.
2. Methyl alcohol: give (*a*) common name, (*d*) uses, (*e*) dangers.

3. Define combustion, and state what takes place when coal is burned.
4. What is fractional distillation?
5. Name four mineral acids used in medicine and give formula of each.
6. Ophthalmia neonatorum: (*a*) etiology and symptoms; (*b*) Credé method of prophylaxis; (*c*) treatment, general and medicinal.
7. Describe Kernig's symptom of cerebrospinal meningitis.
8. Give diagnosis and treatment of acute intussusception.
9. Describe the eruptions in (*a*) chickenpox, (*b*) smallpox, (*c*) measles, (*d*) scarlet fever.
10. Give most common complication in scarlet fever and treatment of same.

OBSTETRICS AND GYNECOLOGY.

1. Describe the uterus, its normal position, its relationship to other organs, and means by which it is held in place.
2. Give symptoms and treatment of placenta prævia.
3. What is phlegmasia alba dolens? At what time does it occur? What is the treatment?
4. What are the danger signals of impending eclampsia? Give treatment of eclampsia at eighth month of pregnancy.
5. Define abortion, miscarriage, and premature labor. Give treatment of an incomplete abortion.
6. Give the etiology and treatment of an acute general cystitis.
7. Define plastic operations as applied to gynecology.
8. What is the differential diagnosis between ascites and ovarian cyst.

PRACTICE OF MEDICINE.

1. Give differential diagnosis between peptic ulcer and carcinoma of stomach.
2. Give physical signs in croupous pneumonia—in the stage of solidification, and differentiate from pleurisy with effusion.
3. In aortic and mitral insufficiency, where is the murmur heard most distinctly, and its direction of transmission?
4. Give etiology of cerebrospinal meningitis, (epidemic) and characteristic symptoms.
5. Define arteriosclerosis, and give chief causes producing it.
6. Give symptoms of hemorrhage in typhoid fever, and treatment.
7. What is the chief cause of locomotor ataxia? Give symptoms briefly in initial and ataxic stages.
8. What conditions are found in examination of urine and circulation in chronic interstitial nephritis?
9. Give briefly treatment for acute articular rheumatism.
10. Write one prescription for local treatment of erysipelas.

SURGERY.

Answer only ten questions.

1. What is pathology and treatment of paronychia?
2. What is pathology and treatment of osteomyelitis of tibia?
3. Describe operation for radical cure of oblique inguinal hernia.
4. Describe operation for acute catarrhal appendicitis.
5. How would you treat a patient who had suddenly ceased to breathe while inhaling chloroform?
6. Describe method of preparing hands for a surgical operation or obstetrical examination.
7. Why do we have abscess of the liver following purulent appendicitis?
8. What is the rule as to fixation of joints above and below a fracture?
9. How do you differentiate between chancre and chancroid? What is period of incubation for each treatment?
10. Describe operation for talipes equinovarus.
11. For the diagnosis of what disease is the Wassermann reaction used?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NORTH CAROLINA BOARD OF MEDICAL EXAMINERS.

June, 1909.

ANATOMY.

1. *Bones of the head:* Occipital, two parietal, two temporal, ethmoid, sphenoid, frontal, two lacrymal, two malar, two nasal, two palate, two superior maxillary, inferior maxillary, vomer, and two inferior turbinated.

The frontal bone consists of a vertical and a horizontal portion. The external surface of the vertical portion is convex, and presents the frontal eminence on either side of the median line; the superciliary ridges, produced by the frontal sinuses, beneath, below which is the supraorbital arch, forming the upper boundary of the orbit, and terminating on either side in the external angular process, articulating with the malar bone and the internal angular process, articulating with the lacrymal bone, and having at its inner third a notch or foramen, the supraorbital foramen, for passage of supraorbital artery, nerve, and vein. Ascending from the external angular process is the temporal ridge for attachment of temporal fascia. Between the internal angular processes is the nasal notch, for articulation with the nasal bone, and nasal process of superior maxilla, terminating below in the nasal spine, and above it projects the nasal eminence, or glabella, marking the location of the frontal sinuses. The posterior surface lodges the anterior lobes of the brain. In the median line is the frontal crest, which gives attachment to the falx cerebri, and terminates below in the foramen cecum. The crest is grooved for longitudinal sinus, and has on either side of it depressions for the Pacchionian bodies. This surface is also grooved for anterior meningeal arteries. The external surface of the horizontal portion is concave, to form the roof of the orbit, and separated from the opposite side by the ethmoidal notch. To the outer side is a depression for the lacrymal gland, and to the inner side one for the pulley of superior oblique. On the margin of the orbital plate are two notches converted into foramina by articulation with the ethmoid, the anterior ethmoidal canal, for passage of nasal nerve and anterior ethmoidal vessels, and the posterior ethmoidal canal, for passage of posterior ethmoidal vessels. The internal surface is marked by the convolutions of the anterior lobes of the brain. Between the two plates of the vertical portion are the frontal sinuses. It articulates with the parietal, sphenoid, ethmoid, nasal, superior maxillary, lacrymal, and malar bones. Its muscular attachments are three pairs—corrugator supercilii, articularis palpebrarum, and temporal. It is developed from membrane.—(After Young.)

2. *The abdominal aorta* commences at the aortic opening in the diaphragm, in front of the lower border of the body of the twelfth dorsal vertebra; it terminates at about the body of the fourth lumbar vertebra, where it bifurcates into the two common iliac arteries. Its branches are: Phrenic, celiac axis (gastric, hepatic, and splenic), superior mesenteric, suprarenal, renal, spermatic (or ovarian), inferior mesenteric, lumbar, and sacra media.

3. *The principal lobes of the brain* are: Frontal, parietal, occipital, temporosphenoidal, Island of Reil, and limbic lobe. The *principal fissures* are: The great longitudinal (separating the two cerebral hemispheres); the great transverse fissure (between cerebrum and cerebellum); the Sylvian fissure; the fissure of Rolando; the parieto-occipital fissure.

4. TRIGEMINUS (fifth cranial nerve). *Origin: Superficial*, from side of pons Varolii; *deep*, from medulla, and floor of fourth ventricle. *Divisions and Functions: First*, ophthalmic; sensory to anterior half of scalp, conjunctiva and skin of upper eyelid, cornea, skin of nose, mucous membrane of nose, lacrymal gland. *Second*, superior maxillary; sensory to conjunctiva and skin of lower eyelid, nose, cheek, upper lip, palate, upper teeth, and alveolar processes. *Third*, inferior maxillary; sensory to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower lip, teeth and alveolar processes of lower jaw. It is also motor to the muscles of mastication (temporal, masseter, two pterygoids), mylohyoid, and anterior belly of the digastric.

5. *The astragalus articulates* with: Tibia, fibula, os calcis, and scaphoid (or navicular).

6. STOMACH is conical, with base to left side; the upper border is concave, and is called the *lesser* curvature; the lower border is convex, and is named the *greater* curvature. The left extremity is known as the *fundus*, above and to the right of which is the *cardiac* orifice, and the right or small end is termed the *pyloric* extremity. It occupies left hypochondriac and epigastric regions. Its *orifices are cardiac*, above, communicating with the esophagus; *pyloric*, at the right extremity, passing into the duodenum. It is 10 to 12 inches long, 4 to 5 inches in diameter at widest part. Its *left* or *cardiac end* is fixed by esophagus and gastrophrenic ligament to diaphragm, lying beneath the seventh left costal cartilage, one inch from sternum; it is connected with the spleen by the gastrosplenic omentum. The *right* or *pyloric end* reaches the gall-bladder, touching under part of quadrate lobe of liver; is very movable; when stomach is empty is in midline four inches below tip of gladiolus. *Anterior surface*, which also looks upward, is in contact with, from left to right, diaphragm, abdominal parietes (epigastric region), under surface of

liver. *Posterior surface* is separated from pancreas, crura of diaphragm, aorta, vena cava inferior, and solar plexus, by lesser sac of peritoneum. *Superior border* is attached to liver by small omentum. *Inferior border* gives attachment to great omentum. *Coronary* and *pyloric* arteries run along lesser curvature; *right* and *left gastroepiploic*, along inferior or greater curvature; *vasa brevia*, from the splenic to fundus. *Right pneumogastric* nerve supplies to posterior surface; *left pneumogastric*, the anterior surface; *sympathetic*, from the solar plexus, both surfaces.—(*Aids to Anatomy.*)

7. Deltoid. *Origin:* From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion process, and from the lower edge of the spine of the scapula. *Insertion:* Into the deltoid impression on the middle of the outer side of the shaft of the humerus. *Action:* It raises the arm from the side so as to bring it at right angles with the body; its anterior fibers draw the arm forward; its posterior fibers draw the arm backward. *Nerve supply:* The circumflex.

Soleus. *Origin:* From back of head of the fibula, and upper part of the posterior surface of shaft of fibula; from oblique line of tibia, and middle third of internal border of tibia. *Insertion:* Into lower part of posterior surface of os calcis. *Action:* To extend the foot, raise the heel; also in walking, standing, dancing. *Nerve supply:* Internal popliteal and posterior tibial.

Quadratus lumborum. *Origin:* From iliolumbar ligament, crest of ilium, and transverse processes of three or four lower lumbar vertebræ. *Insertion:* Into lower border of twelfth rib and transverse processes of four upper lumbar vertebræ. *Action:* It draws down twelfth rib, flexes spine laterally. *Nerve supply:* Anterior branches of lumbar nerves.

8. *Femoral hernia* leaves the abdomen through the femoral ring and descends into the femoral canal; this canal is funnel-shaped, is about half an inch in length, and ends at the saphenous opening. Femoral hernia is always *acquired*, and has a sac. Its course is first vertical, then forward, then upward over Poupart's ligament. Its coverings, from without inward, are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum. The neck of the hernia is situated at the femoral ring; to its outer side lies the femoral vein, and to its inner side is Gimbernat's ligament; in front of it is Poupart's ligament, and behind it are the pubis, the Pectineus, and the pubic portion of the fascia lata. In the immediate neighborhood of the femoral ring are: Anteriorly, the communicating branch between the deep epigastric and the obturator arteries; externally, the femoral vein and deep epigastric vessels; superiorly, the spermatic cord (or round ligament) and the deep epigastric vessels.

9. The *ovaries* are two in number, and correspond to the testes in the male; they are of a flattened ovoid form, vertically placed in the posterior part of the broad ligament. By its anterior border the ovary is connected to the broad ligament, and by its lower pole to the uterus by a proper ligament, extending to the superior angle of the uterus, and called the *ligament of the ovary*. The lateral surfaces and posterior borders are free. The superior pole and posterior border are embraced by the Fallopian tube; on its inner surface it is in relation with small intestine in Douglas' pouch, and externally lies in a peritoneal fossa between the external and internal iliac vessels as they diverge. The vessels enter the hilum at the attached anterior border.—(*Aids to Anatomy.*)

10. An *artery* consists of three coats: The tunica interna, or internal coat; the tunica media, or middle coat, and the tunica adventitia, or external coat. The internal coat consists of a basement membrane, on which is a layer of endothelial cells. The middle coat consists of involuntary muscle fibers, between the layers of which are some elastic fibers. The external coat consists of connective tissue (white fibrous and yellow elastic). Between the two outer coats is an elastic membrane.

11. The *rectum* is the lowest part of the alimentary canal, and extends from the sigmoid flexure to the anus. It is about six inches in length, and is divided into three portions. The upper half only is invested with peritoneum. The upper third rests upon the sacral plexus and the pyriformis muscle; the middle third is in relation with the bladder, prostate, and seminal vesicles (in the female with uterus and vagina); the lower third is surrounded by the sphincters. It is not sacculated; the arteries are the hemorrhoidal branches of the inferior mesenteric, internal iliac, and internal pudic; the veins form the hemorrhoidal plexus, and empty into the inferior mesenteric and internal iliac veins.

12. The *iris* is a thin, circular, colored membrane suspended in the aqueous humor, behind the cornea and in front of the lens. It is perforated by a circular aperture—the pupil. It is connected with the choroid, the sclerotic, and cornea. It consists of a stroma of connective tissue, with blood vessels, nerves, pigment cells, and also two groups of involuntary muscle fibers—circular and radiating. *Blood supply:* Long and anterior ciliary arteries, and short ciliary arteries. *Nerves:* Ciliary, from lenticular ganglion and nasal branch of ophthalmic division of fifth cranial nerve.

PHYSIOLOGY AND HYGIENE.

1. Evidence that the secretion of the urine is not a simple process of filtration from the blood rests mainly on the following facts:

"1. It has been shown that the renal epithelium does excrete indigo carmine from the blood when a solution of this material is injected into the veins; by dividing the spinal cord to prevent the excretion of water, which would wash away the indigo carmine, after allowing an appropriate time to elapse before killing the animal, the epithelium of the convoluted tubules will be found loaded with the indigo carmine.

"2. In the amphibia (frogs, newts, etc.), the kidney has a double vascular supply; the glomeruli of the Malpighian bodies are supplied by the renal arteries, and the capillaries of the renal tubules by veins called renal portal veins. By tying the one or the other set of vessels and injecting various materials into the blood it has been shown that urea is only excreted by the cells of the tubules, and that sugar, peptones, and albumins are only excreted by the glomeruli."—(*Aids to Physiology.*)

The nerves are both *vasodilator* and *vasoconstrictor:* true secretory nerves have not yet been discovered.

2. For structure of the three coats of an artery, see above, Anatomy 10. Veins also have three coats, arranged similarly to those of arteries, but the middle coat possesses less elastic and muscle tissue and more fibrous tissue, hence the tendency of veins to collapse when empty. In veins the external coat is the thickest; in arteries the middle coat is the thickest. Veins have valves, as a rule. Functions of the endothelial lining of the inner coat is to make a smooth surface for the circulation of the blood with as little friction as possible. The muscular fibers supply contractility. The elastic fibers supply elasticity. The connective tissue fibers supply strength and support.

3. The principal centers of organic function situated in the medulla are: (1) Center for mastication; (2) for secretion of saliva; (3) for sucking; (4) for deglutition; (5) for vomiting; (6) for voice; (7) center for expression; (8) cardiac centers; (9) respiratory centers; (10) vasomotor centers.

4. Leucocytes. (*a*) *Origin:* Supposed to be formed in the spleen, lymph glands, and lymphoid tissue. (*b*) *Functions:* (1) To serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma. (*c*) *Variations in number:* Normally between 7,000 and 10,000 or 12,000 in each cubic millimeter of blood.

5. The *function of the carbohydrate food* is to supply animal heat and energy; also to form fats and possibly to help form proteids.

6. *Enzymes* (*a*) are substances formed by living cells, which act specifically upon definite substances, and which themselves remain unchanged during this action. Their specific action is shown in the following table. Enzymes are generally soluble in water or saline solution; they act best at about the body temperature, and are destroyed by high temperatures; excess of alcohol tends to precipitate them from their solutions; the enzymes can act almost indefinitely, but the products of their activity must be removed. (*b*) *Six principal enzymes:*

ENZYMES	ORIGIN	ACTION ON FOOD MATERIALS
Ptyalin.	Saliva.	Changes starches into dextrin and sugar.
Pepsin.	Gastric Juice.	Changes proteids into proteoses and peptones in an acid medium.

ENZYMES	ORIGIN	ACTION ON FOOD MATERIALS
Trypsin.	Pancreatic Juice.	Changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; in an alkaline medium.
Amylopsin.		Converts starches into maltose.
Steapsin.		Emulsifies and saponifies fats.
Invertin.	Intestinal Juice.	Converts maltose into Glucose.

7. (*a*) *Nitrates* are generally due to oxidation of organic matter of animal origin. A trace of nitrate, not exceeding N = 0.35 per 100,000, would not suffice to condemn a water otherwise pure. (*b*) *Nitrites* are due to sewage contamination; their presence should condemn the water. They indicate more recent and therefore more dangerous contamination than nitrates.

8. *Prophylaxis of uncinariasis* consists in: (1) Boiling the drinking water; (2) washing of the hands before meals; (3) not going barefooted; (4) disinfection of the stools of all infected persons.

9. *Municipal supervision of a city's milk supply.* Theoretically, this should be desirable, because: (1) Milk is adulterated very frequently; (2) diseases are conveyed through milk; (3) cowsheds, dairies, and milkshops are often in a most unsanitary condition; (4) persons suffering from infectious diseases are occasionally employed in the milking or storage or distribution of milk. Municipal supervision *might* prevent all of this. But experience shows that municipal authorities are not always any more keen than others in doing their duty; graft, persecution, and tyranny might result; the price of milk would be unduly raised, and every political evil might reign supreme. If these evils can be prevented, municipal supervision would be most desirable.

10. The air is contaminated by *combustion* (in which oxygen is decreased, and there are given off: Nitrogen, carbon dioxide, ammonia, sulphur dioxide, and carbon monoxide); *respiration* (in which oxygen is decreased, carbon dioxide is increased, ammonia and organic matter are produced). *Improper ventilation* increases all these evils. Various diseases are directly produced, or indirectly induced.

MATERIA MEDICA.

1. (*a*) *Cholagogues* influence the liver; (*b*) *sialagogues*, the salivary glands; (*c*) *oxytocics*, the uterus; (*d*) *diaphoretics*, the sweat glands; (*e*) *mydriatics*, the eye.

2. (*a*) *Epsom salts* is Magnesii sulphas; (*b*) *Dover's powder* is Pulvis ipecacuanhæ et opii; (*c*) *calomel* is Hydrargyri chloridum mite; (*d*) *salol* is Phenylis salilylas; (*e*) *Fowler's solution* is liquor potassii arsenitis; (*f*) *Hoffmann's anodyne* spiritus ætheris compositus; (*g*) *cod liver oil* is Oleum morrhuæ; (*h*) *sulphonal* is Sulphon-methanum; (*i*) *aristol* is Thymolis iodidum; (*j*) *spirit of nitroglycerin* is Spiritus glycerylis nitratis.

3. A *tincture* is an alcoholic solution of a medicinal substance. (1) Tincture of aconite, 10 per cent. (2) Tincture of nux vomica, 2 per cent. (3) Tincture of iodine, 7 per cent. (4) Tincture of digitalis, 10 per cent.

4. Doses. (*a*) Apomorphinæ hydrochloridum, gr. 1/10, as an emetic. (*b*) Arseni trioxidum, gr. 1/30. (*c*) Chloralum hydratum, gr. xv. (*d*) Atropinæ sulphas, gr. 1/60. (*e*) Hydrargyri chloridum corrosivum, gr. 1/20. (*f*) Strychninæ sulphas, gr. 1/64. (*g*) Hexamethylenamine, gr. iv. (*h*) Tinctura aconiti, ♏x. (*i*) Tinctura gelsemii, ♏viii. (*j*) Glandula suprarenalis sicca, gr. iv.

5. Specific treatment for diphtheria is diphtheria antitoxin; dose, 3000 units; immunizing dose for well persons, 500 units.

The serum of the blood of the horse, immunized by repeated injections of diphtheria toxin from cultures of the bacillus.

6. Specific remedy for myxedema—dry thyroid of the sheep.

7. *Prescription for Dysentery:*

℞ Acidi sulphurici aromatici, ℥jss.
Spiritus chloroformi, ℥ij.
Tincturæ opii camphoratæ, ℥ij.
Syrupi zingiberis, q.s. ad ℥iv. Misce.
Signa: Dessertspoonful in water every two hours.

8. For local applications in tonsillitis. Alum, guaiacol, hydrogen peroxide, nitrate of silver.

9. Poisoning may be produced by: (1) Illuminating gas, (2) headache powders, (3) ptomaines, (4) snake bite, and (5) fungi (mushrooms, toadstools).

10. *Antidote* for (*a*) bichloride of mercury is white of egg or milk; (*b*) for arsenic, is freshly prepared solution of ferric hydroxide; (*c*) for iodine, is starch paste; (*d*) for opium, is caffeine, or strychnine.

CHEMISTRY AND DISEASES OF CHILDREN.

1. Since C = 5/9 (F − 32), C = 5/9 (104 − 32) = 5/9 of 72 = 40°.
Therefore 104 Fahrenheit = 40° Centigrade.
(*b*) One grain = 0.005 gram.

2. Methyl alcohol. (*a*) *Common name:* Wood spirit. (*b*) *Uses:* Solvent of resins, sulphur, phosphorus, potash, soda, and volatile oils. (*c*) *Dangers:* It should not be used in pharmacy, or taken internally, even when purified, for it has caused blindness and death.

3. *Combustion* is rapid oxidation with the giving off of light and heat. When coal is burned, the carbon unites with the oxygen of the air, producing carbon monoxide and carbon dioxide; other gases and liquids are also given off, and the coal is decomposed and gradually disappears, only some ashes being left.

4. *Fractional distillation* is a process by which liquids with different boiling points may be separated in a pure condition; it is largely used in the separation of coal tar products. The temperature of the mixture is gradually raised, so that the components are distilled off successively in the order of their volatility.

5. *Four mineral acids:* Hydrochloric acid, HCl; nitric acid, HNO_3; sulphuric acid, H_2SO_4; phosphoric acid, H_3PO_4.

6. Ophthalmia neonatorum. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

7. Kernig's symptom of cerebrospinal meningitis consists in the fact that if the thighs or legs are flexed they cannot then be fully extended, owing to the contracture of the muscles on the posterior of the thigh.

8. Acute intussusception. *Diagnosis:* Sudden onset, severe localized pain, vomiting, tenesmus, and passage of bloody mucus. There is a sausage-like tumor in the abdomen; sometimes it can be felt in the rectum. Fecal impaction or appendicitis may simulate it, but in the former the swelling is less tender and is on the left side; in the latter there is fever, and the tumor is on the right side. *Treatment:* Laparotomy and reduction of the bowel as soon as possible. Gentle manipulations, enemata, and opium have been suggested, but these should be adopted only when surgical relief is not available.

9. (*a*) *In chickenpox:* The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured. (*b*) *In smallpox:* The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin. (*c*) *In measles:* Eruption appears on fourth day as small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny. (*d*) *In scarlet fever:* Eruption appears at end of twenty-four hours, as a scarlet puncture rash, beginning on neck and chest then covering face and body; desquamation is scaly or in flakes.

10. Most common complications of scarlet fever are: Arthritis, endocarditis, bronchopneumonia, ear troubles (perforation, deafness), facial paralysis or meningitis.

suppuration of cervical glands, nephritis. *Treatment,* as a rule, same as in nonscarlatinal cases; warm and sedative applications, with cotton wool for arthritis, also alkalies; for the throat, ice to suck, warm applications externally, antiseptic sprays; tonics and stimulants. A minimum of nitrogenous food to avoid irritating the kidneys. For the nephritis: The patient should be kept in bed, kept quiet, and kept warm. Milk diet should be the rule; the milk can be diluted with limewater or Vichy. Salines, as potassium bitartrate or magnesium citrate or sulphate, and diaphoretics, as sweet spirit of niter, or pilocarpin, may be administered. Warm baths are helpful, and infusion of digitalis should be given.

OBSTETRICS AND GYNECOLOGY.

1. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, and rectouterine.

2. The *symptoms* of placenta prævia are: Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Treatment:* Stop the hemorrhage by a vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

3. *Phlegmasia alba dolens* is a form of manifestation of puerperal sepsis in which there is a thrombosis of the iliac or femoral vein. Sometimes it occurs after a uterine phlebitis, in which clots are carried from the uterine sinuses to the hypogastric veins, where they cause obstruction to the blood flow in the crural veins. The trouble may also begin as a crural phlebitis. It is thus due either to cellulitis or to thrombosis. It usually appears about the third or fourth week of the puerperium. *Treatment:* Liquid and nutritious diet, tonics, stimulants, mild laxatives, opiates, or hypnotics, absolute rest in bed; the affected limb should be slightly elevated; laudanum or belladonna poultices may be applied. An elastic bandage should subsequently be worn.

4. *The danger signals of impending eclampsia* are: Headache; tinnitus aurium; dizziness; pain over stomach; digestive, visual, and nervous disturbances; general debility; insomnia, vomiting, and vertigo. For *preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. The *curative treatment* includes: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

5. *Abortion* is delivery of the product of conception before the twelfth week.

Miscarriage is delivery of the product of conception between the twelfth and twenty-eighth weeks.

Premature labor is delivery of the fetus between the twenty-eighth week and full term.

Treatment of an incomplete abortion: Anesthetize the patient, dilate the cervix, with finger or curette remove all débris, irrigate with saline or antiseptic solution, and keep in bed.

6. ACUTE CYSTITIS. (*a*) *Etiology:* Various pathogenic bacteria, foreign bodies, traumatism, retention of urine, unclean catheters, cold. (*b*) *Treatment* includes: Rest, administration of plenty of cold water or milk, diuretics, bland and mild food, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.

7. *Plastic operations in gynecology* are such as are done: (1) for the repair of lacerations of the perineum or cervix; (2) for vaginal fistulæ; (3) for the narrowing of the vagina, and the treatment of cystocele or rectocele; and (4) various other operations on vulva, urethra, or anus.

8.

ASCITES	OVARIAN CYST.
1. Previous history of visceral disease.	1. No such history.
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovariana. Anemia absent, or later.
4. Patient on back, enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change.
6. Navel prominent and thinned.	6. Navel usually unchanged.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity, and dulness in lowest parts for all positions—*i.e.* areas of resonance and dullness change with position.	8. No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency: albuminous, but does not coagulate spontaneously; may contain colloid matter.

—(From Dudley's *Gynecology.*)

PRACTICE OF MEDICINE.

1. *Peptic ulcer* is generally caused by injury or bacteria; is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating; hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

Carcinoma of the stomach does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious, and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

2. In croupous pneumonia, in the stage of solidification, the physical signs are: Diminished chest movement; increased vocal fremitus; absence of vesicular breathing, presence of tubular breathing, increased vocal resonance, bronchophony, or pectoriloquy; dullness on percussion.

ACUTE PNEUMONIA.	EXUDATIVE PLEURISY.
Onset very sudden and symptoms severe—convulsions, etc., cough first, followed by pain in the side.	Onset moderately sudden, and symptoms not severe—chilliness and pain in the side, followed by cough.
Temperature very high, 104° or often 105° F.	Temperature not high, 101.5° or 102° F.
Pulse-respiration ratio greatly disturbed.	Pulse-respiration ratio not disturbed.
Bright crimson flush on the cheeks, and the muscular prostration is considerable.	Face is pale, and there is little loss of muscular power.
Cough is short and hacking or in paroxysms; and the sputum, when brought up, is rusty and tenacious.	Cough is dry and painful, and patient tries to repress it.
Organs not displaced.	Organs displaced.

ACUTE PNEUMONIA.	EXUDATIVE PLEURISY.
Dullness on percussion not complete, and the sense of resistance almost nil.	Dullness complete, with sense of great resistance.
Respiratory sounds tubular, and fine crepitation heard at border of consolidation.	Respiratory sounds much diminished, and friction heard at upper margin of effusion.
Vocal resonance increased.	Vocal resonance greatly diminished.
Vocal fremitus increased.	Vocal fremitus diminished or absent.
The physical signs are limited to the front or back of the chest.	The physical signs are found both at the back and front of the affected side

3.

	MURMUR HEARD BEST.	TRANSMITTED.
Aortic Insufficiency..	Second right intercostal space.	Down sternum, and towards apex.
Mitral Insufficiency..	At apex.	Left axilla and angle of scapula.

4. CEREBROSPINAL MENINGITIS. *Etiology:* The diplococcus intracellularis of Weichselbaum, or streptococcus pyogenes, or pneumococcus.

Characteristic symptoms: Sudden onset, very severe pain in neck, back of head and spine, head is strongly retracted, causing opisthotonos, Kernig's sign (see above, CHEMISTRY, No. 7) is present; delirium may be present; the diplococcus may be found in the cerebrospinal fluid.

5. *Arteriosclerosis* is a condition in which the walls of an artery, especially the intima, become hard, dry, and thickened.

Etiology: Syphilis, alcoholism, gout, Bright's disease, overeating, and excessive muscular exertion. It is most liable to occur in old age.

6. *Symptoms of hemorrhage in typhoid fever:* Sudden drop in the body temperature, dark red or tarry stools, collapse.

Treatment: Absolute rest; elevate the foot of the bed: ice, morphine, and ergot have all been used with satisfaction.

7. *The chief cause of locomotor ataxia* is syphilis.

Symptoms: Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil.

8. In *chronic interstitial nephritis* the *urine* is increased in quantity, is of low specific gravity, a few hyaline casts may be present, albumin is present in small amount or is absent, and urea and salts are diminished.

Circulation: Heart is generally hypertrophied and dilated; arteries are sclerosed and thickened; pulse is hard and there is increased arterial tension.

9. *Treatment of acute articular rheumatism:* The patient must lie in bed, between blankets, and in flannel; the affected joints and limbs must further be covered with warm flannel or cotton wool. Sodium salicylate or oil of wintergreen must be administered, and oil of gaultheria may also be applied locally to the affected parts. Acetate and citrate of potassium are also useful. For the pain, Dover's powder, or phenacetin, or morphine may be necessary. A cold bath is probably the best thing for the high fever. The diet should be liquid, and simple but nourishing; milk being the best.

10. *Prescription for local treatment of erysipelas:*

℞ Ichthyol, gr. xxxv.
Resorcin, ʒss.
Unguenti hydrargyri, ʒiv.
Adipis lanæ hydrosi, ʒv. Misce.
Signa: Apply freely, and cover with lint.

SURGERY.

1. *Paronychia* is a cellulitis beginning at the end or side of the finger and involving the parts around and below the nail. The pus organisms enter through a puncture, an abrasion, or an ulcerated hang-nail. *Treatment* is free and early incision, drainage, antiseptic dressings, tonics, and stimulants. The nail may or may not have to be removed.

2. OSTEOMYELITIS OF TIBIA. *Pathological Changes:* "The area of the medulla affected becomes hyperemic; exudation occurs in the cancellous spaces, Haversian canals, and under the periosteum. Pus soon forms in these three situations. If the disease begins in the superficial part of the bone, the pus may only be subperiosteal, the deeper part of the bone escaping, though large areas of the superficial portion may die from the combined action of (1) stripping up of the periosteum by the pus, (2) strangulation of the vessels in the bone by the pressure of the exudation, and (3) the toxic action of the bacterial products. . . . When the disease begins in the deeper layers of the bone, the pus may reach the periosteum, or extend along the medullary cavity, so that the veins become filled with septic thrombus, which may be disintegrated and carried off as septic emboli (pyemia). There is profound toxemia, and necrosis of the whole diaphysis may occur. . . . If the infection is mild, a chronic abscess may be formed in the cancellous tissue. The usual course of an acute case, if a patient survives, is that there is some necrosis of the shaft of the bone. The abscess bursts externally, and there are numerous openings in the skin leading through openings (cloacæ) in the periosteum and involucrum down to the sequestrum. The sequestrum becomes loose in six weeks to six months." (From *Aids to Surgery.*)

Treatment is immediate incision down through the periosteum; the surface of the bone must be opened with gouge or chisel, pus evacuated, and drainage instituted; irrigation with hot bichloride solution and packing with gauze. The medulla of the bone must be freely exposed, and any suppurating material removed. Constitutional treatment and rest are, of course, indicated.

3. "Many operations are practised, but Bassini's is the most useful. An incision 2½ inches long is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three or four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterwards for six months." (From *Aids to Surgery.*)

4. For operation, see any text-book on Surgery.

5. Stop the administration of further chloroform, open the patient's mouth, draw out his tongue, start artificial respiration. Mouth and throat must be sponged out if necessary; a hypodermic injection of strychnine, ether or brandy may be given, but the artificial respiration must not be stopped.

6. *To prepare the hands:* The hands and forearms should be rubbed with spirits of turpentine; then scrubbed with castile soap, hot water, and a sterilized nail brush; this should continue for several minutes; thorough rinsing must follow; the hands are then to be soaked for two minutes in a 1:1,000 bichloride of mercury solution. Care must then be taken lest the hands touch anything that is not sterile.

7. Abscess of the liver may occur after purulent appendicitis, owing to the possibility of infection from the appendix reaching the liver through the portal vein, or through the lymphatics.

8. The joints both above and below a fracture should always be immobilized.

9.

CHANCRE.	CHANCROID.
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.

CHANCRE.	CHANCROID.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

The period of incubation of *chancre* is anywhere from two to six weeks after infection; of *chancroid* is about two to five days after infection.

10. PHELPS' OPERATION. *Step* 1.—Render limb bloodless by elevation and apply tourniquet. Place the foot, with outer side downwards, on a sand-bag. Have the heel held firmly. Grasp the distal portion of the foot and make the plaster tissues tense. *Step* 2.—On the inner side of the foot make an incision beginning directly in front of the malleolus and ending one-fourth of the distance across the sole of the foot. Divide *all* resisting structures, penetrating to the bone if necessary. *Step* 3.—By manipulation complete the overcorrection of the varus. *Step* 4.—Correct the equinus by achillotomy. *Step* 5.—Pack the wound with iodoform gauze. Dress. Immobilize, in a position of overcorrection, by a plaster-of-Paris bandage, which reaches well up the calf. While the plaster is hardening, hold the foot in its new position by means of a flat board laid against the sole. *Step* 6.—Remove the tourniquet. Elevate the limb for twenty-four hours.

11. The Wasserman reaction is used for the diagnosis of syphilis.

BULLETIN OF APPROACHING EXAMINATION.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. —
Arizona*	Ancil Martin, Phoenix	Phœnix	Jan. 3

THE TREATMENT OF PULMONARY TUBERCULOSIS BASED ON THE ASSUMPTION THAT THE DIETETIC CAUSE OF THE DISEASE IS LIME STARVATION.

PRELIMINARY REPORT OF RESULTS.

By JOHN F. RUSSELL, M.D.,

NEW YORK

LIME forms about three-quarters of the total mineral solids of the body. It is found in all tissues and fluids and certain of its salts are necessary for physiological activities. Because of this widespread occurrence and specific influence on body processes, and because certain conditions of ill health are associated with a lessened amount of lime in the organs, it has naturally been a subject of speculation whether disease may not be the result of a deficient supply of this element.

The chief lime-bearing food is milk which has been prescribed in the treatment of the tuberculous since the earliest times. Next to milk, eggs contain the greatest amount of lime. Milk and eggs are largely employed in the modern dietetic treatment of tuberculosis.

The most important salt of lime is the insoluble phosphate. How is this salt rendered absorbable in a form available for use by the tissues?

The manner of the absorption of phosphate of lime is not explained by physiologists. It is however, stated that its absorption in an assimilable form is best assured when it is administered in combination with proteid substances.[1] In other words, when phosphate of lime is in chemical union with proteid, this combination is acted upon by the gastric enzymes and prepared for absorption in a condition suitable for nutrition.

Because phosphate of lime is soluble in acid solutions it has been suggested that after being brought into solution by the acid gastric contents it is absorbed without further change as an inorganic salt. The correctness of this conception has been denied on the ground that the salt would remain in solution only so long as the fluid remained acid; that it would at once be precipitated by the alkaline fluid of the intestines, or, if it succeeded in reaching the blood, by the alkaline serum containing dibasic sodium phosphate.[2] On the other hand it has been demonstrated that the alkaline blood-serum has the property of holding earthy phosphates in solution.[3]

Inorganic material occurs in the body partly dissolved in the fluids and partly combined with organic substances. It appears not to be certainly known in which of the two states these substances are assimilated by the tissues. It is conceivable that insoluble salts like phosphate of lime, unless in chemical combination with proteid, circulate and are eliminated unused by the tissues, because presented to them in an unsuitable form. Lime phosphate in the blood serum is found in combination with albumin and circulates as lime albuminate.[4]

It is a matter of common observation that the outcome of treatment in a given case of pulmonary tuberculosis cannot be predicted with certainty, far-advanced, extensive disease, often clearing in the most surprising manner while, on the other hand, cases are occasionally seen in which the lesion localized within narrow limits, remains unchanged after years of treatment, or, becoming active, extends and finally overwhelms the patient. The difference in outcome of these cases cannot always be explained by differences in age, sex, habits, occupation, or surroundings.

Since the beginning of my dispensary work in the treatment of pulmonary tuberculosis, March 14, 1898, milk has formed a large part of the diets. Eggs were added a few years later. During this time a number of patients have been apparently cured; a number have failed to receive substantial benefit; a number have failed to receive any benefit at all. How can these differences be explained by the supposition that lack of lime is a dietetic cause of tuberculosis?

In the summer of 1906, while speculating on the manner of the absorption of the lime in milk it occurred to the writer that if the gastric secretion lacked rennet, combination of lime and casein would not take place and the lime would not then be absorbed in a form suitable for tissue nutrition. That is, without the action of rennet it would not be brought into proper combination with proteid. This suggested a possible explanation of the failures above mentioned. The successes were explained on the assumption that either the gastric secretion of these patients was normal and they had, previous to treatment, received an insufficient supply of lime-bearing food which would yield this combination or, their gastric secretion not being quite normal, due to an inconstant secretion of acid in amount necessary to produce rennet, these patients had received sufficient acid in the food prescribed (raw milk for example) to activate rennet-zymogen and thus insure the lime combination necessary.

Two ways by which lime starvation may be produced were therefore suggested: First, as a result of lack of supply, gastric secretion being sufficient. Secondly, supply being ample, as a result of failure to form proper combination with proteid during digestion because of an inefficient gastric secretion.

The treatment about to be described was worked out from two purely hypothetical considerations, viz., First, that lime starvation may be the dietetic cause of tuberculosis. Secondly, that the action of rennet in the stomach is necessary in the prepar-

ation of lime for absorption in a form suitable for the growth and repair of tissue. The treatment and its results will first be described. The discussion of the hypotheses will be considered in another article.

The separation of tuberculous patients into two classes, (1) those whose disease is the result of a deficient supply of proper food and (2) those whose disease is the result of a deficient production of rennet, can only be made by observing the results of treatment. Upon examination there are no signs by which one can certainly say that a patient falls into one or the other class. Again, it is improbable that digestion is perfectly normal in patients of the first class named. The probabilities are all in favor of the view that the two conditions, viz., lack of supply of proper food and lack of adequate rennet production, often exist together in the same patient and in varying degree. While the disaster may be as great in the one case as the other, it is obvious that the difficulties of treatment are much increased when the fault lies with digestion. The treatment of the latter condition fulfills the requirements of the former so that the treatment of all patients is conducted on the assumption that their lime starvation is due to the imperfect action of rennet in the stomach.

The daily amount of lime required to maintain the body in health presumably varies with different periods of growth and development. It has been calculated that an infant requires about five grains daily.[5] The amount required by an adult, whether healthy or diseased, is unknown. In these investigations it was at first assumed that one quart of cow's milk, which contains about 23 grains of lime salts of various kinds, plus the usual number of eggs, would provide a plentiful daily amount of lime phosphate.

As the result of this speculation, the investigation here described was begun Sept. 12, 1906. All patients under treatment at the writer's dispensary were directed to drink one quart of junketed milk daily. The method of clotting was demonstrated to each patient who was then given a quantity of commercial rennet and instructed to clot and drink the milk at home.* Milk to be clotted as soon as received in the morning and at once put in the ice chest. When about to drink, the quantity to be consumed, whey and clot together, to be poured into a bowl and the clot beaten into small particles by an egg beater, and drunk. No additional milk was prescribed. The only change in treatment from that heretofore employed was that the daily amount of milk was restricted to one quart which was clotted by rennet.

During the following December and January the occurrence of fibrinous or plastic pleurisy about the site of disease was noted. Observed first in a few patients the number increased as time went on to such an extent as to suggest that these attacks were produced by, or were in some way connected with, clotted milk. It was further observed that, after an uncertain time, the pleurisy was followed by marked improvement and final disappearance of all signs of the original disease. All patients, however, did not develop signs of plastic pleurisy and the amount and extent of effusion varied in those who did.

This effusion came to be regarded as a manifestation of a healing process—a plastic effusion. It, therefore, became of the greatest importance to determine, first, whether its occurrence was certainly due to the intake of clotted milk; secondly, the means by which it could be produced in sufficient quantity in all patients. These investigations consumed more than a year (Nov. 25, 1907) before the first question was answered positively in the affirmative, and eight months additional (July 21, 1908) before the method as at present practised was reached. A great many experiments were tried without success in both instances, a description of which is omitted (with one exception) because of lack of space. This experiment was as follows.

Thinking that the failure to develop plastic effusion more certainly might be due to an insufficient amount of combined lime phosphate and proteid in the diet the administration of ground chicken bone* was begun. This substance was selected for two reasons: First, because a small amount (one drachm twice daily) contained a large extra amount of combined lime without proving a burdensome addition to the bulk of the diet. Secondly, while it is not stated that the combination of lime and the organic material of bone is chemical I think the feeling generally is that it is most probably so though the union is very loose. The administration of this substance extending over many months gave no noticeable result.

As before stated the use of clotted milk instead of plain milk was the only radical change in treatment, except that the daily amount was limited to one quart. Failure to show effusion was noted particularly among pateints who had been under treatment a long time previous to the use of junketed milk. A number had been under treatment for years as will be seen on consulting the table. Though the general improvement in these patients was marked their lung lesion remained unhealed. Obviously the production or non-production of plastic effusion in these patients became the test of the efficiency of any measure tried. These patients were regardd as xamples of deficient rennet secretion because it was certain an ample supply of lime had been provided in their previous treatment.

Experiments were continued until all patients, old and new, showed signs of plastic effusion. Briefly, this result followed the administration of dilute hydrochloric acid (U.S.D.) in conjunction with plain milk, and rennet-clotted milk was discontinued. The dose of acid and the best method of administering it was determined only after long experimentation, as before stated.

The symptoms of plastic effusion are the symptoms of acute pleurisy and vary in intensity in different patients. They begin with pain, temperature, and physical signs of pleurisy. Pain may be slight or severe, temperature may be only slightly elevated or in some cases reach 102° and higher. The acute

*The greater number of patients clotted and drank the milk at home: two glassful after morning and evening meals. Many patients, particularly those without family, found it convenient to have the junket made at the dispensary and drank it there. This was required of a few who, it was suspected, failed properly to prepare it at home. It was finally found necessary in order to insure accuracy, to administer at the dispensary everything which was being experimented with. This was inauguarated July, 1907.

*Ground chicken bone was prepared as follows: Uncooked plucked chickens were plunged into boiling water and held there for a few moments in order to clean the skin, and then placed upon a table where the bones were dissected out and ground to a pulp. These operations were conducted with the greatest care as regards cleanliness. The pulp was then mixed with sterile glycerine and enough pepsin worked into the mass to yield five grains to each dose. The mixture was then put into glass-stoppered sterile bottles and a few drops of oil of peppermint added.

symptoms may last a week, more or less. Physical signs vary in intensity. As a rule the more marked the lung lesion the more marked the physical signs of pleurisy. After the acute symptoms subside and the effusion begins to organize, creaks and dry rubs are marked. Most râles gradually disappear.

As the original lesion heals the most marked signs of effusion may either disappear altogether or persist for some time after. As a rule the more extensive the original lesion the longer the signs of organized effusion remain. This is true particularly over and about cavities. Serous effusion has so far never been noted. The time at which these symptoms first make their appearance varies. Broadly speaking, it may be put for the majority at between the sixth and sixteenth week after beginning treatment. Plastic effusion occasionally occurs in situations where no lesion had previously been noted. It may occur more than once in the same patient. In a few instances the effusion has been accompanied by signs of a pneumonia.

The use of hydrochloric acid was begun Nov. 25, 1907. Every patient then under treatment and every patient since admitted who has remained a sufficient length of time, has developed plastic pleurisy. Because of this experience its appearance is now confidently predicted in every new patient. The result is that such patients look forward to its occurrence and regard the first attack of pain as evidence of progress toward cure.

Treatment.—The special aim of treatment is to supply lime phosphate, casein, and hydrochloric acid together. Neither alone will answer. They must all be present in the stomach at the same time. The addition of dilute hydrochloric acid to milk and eggs accomplishes this endeavor. With the exception that vegetable juice is no longer prescribed and that the total amount of food consumed is less, the use of this acid is the only notable change made in the treatment heretofore employed.* The treatment has been published so often that it is not necessary to describe it further here.

Preparation of the milk-egg-acid mixture. At the dispensary two eggs are beaten, strained and mixed with sufficient milk to make one quart. To each quart of this mixture four drachms of dilute hydrochloric acid (U.S.D.) are added and stirred until thoroughly mixed. The mixture is then bottled and put in the ice chest. Patients drink one pint at the morning hour and one pint at the evening hour. The appearance of the curd varies. The warmer the milk and egg mixture when hydrochloric acid is added the thicker the curds. The curds are, therefore, sometimes thicker and more noticeable than at others but are always soft, rather fine, and in no way disagreeable to drink. Unlike rennet-clotted milk this mixture does not require beating before being drunk. The taste of raw egg is much improved by the acid.

Dose of acid. The dose given above was adopted after experiments which consumed a long time. The largest dose administered was nine drachms fifteen drops in each quart. This amount was continued from April 15, 1909, to June 5, 1909. No better effects were observed during this period than when the smaller dose was employed. It was, therefore, reduced in amount.

*Vegetable juice, glycerin, and calcium chloride have been discontinued. It is now probable that the good effects of vegetable juice were chiefly due to its acidity; of glycerin to its power of extracting enzymes. Calcium chloride is formed in milk when hydrochloric acid is added.

There are three reasons for the administration of hydrochloric acid: First, to activate rennet zymogen. Secondly, to activate pepsin zymogen. Thirdly, to stimulate the secretion of pancreatic juice by means of secretin. After the combination of lime and casein has been brought about by rennet the action of pepsin is necessary in order to prepare this combination for absorption in an assimilable form. If it is true that the tuberculous suffer from lack of free rennet in the stomach secretion it must be true also that there is a deficient secretion of free hydrochloric acid, as will be shown later. In such case pepsin will not act. Clearly, therefore, the administration of rennet-clotted milk does not meet all the requirements. It is thought that this is the explanation of the failure of certain patients to develop plastic effusion while taking rennet-clotted milk.

Pancreatic juice contains rennet and its action clots milk. It was found by experiment extending over a long period of time that the administration of milk previously clotted by pancreatin produces plastic effusion. Two experiments were tried, one in which whole milk clotted by pancreatine was administered, the other in which skim milk digested by pancreatin was administered. In both experiments plastic effusion developed but its occurrence was less certain and less extensive than resulted from the employment of rennet-clotted milk. The use of pancreatin was, therefore, discontinued. Nevertheless the fact that the administration of milk clotted by pancreatin was followed by plastic effusion is an additional reason for desiring the complete action of pancreatic juice.

The reason for thoroughly mixing the acid and food before introduction into the stomach, instead of administering each separately, is suggested by the lack of equable intermixture of the stomach contents. It has been demonstrated on animals that food remains in separate, distinct layers in the stomach, nearly to the end of digestion.[6] This is true of both solids and liquids. In the experiments just mentioned it was found that the degree of acidity was greater at the periphery of the mass than at the center, the latter portion often showing no acid reaction to litmus. In case of deficient secretion of acid it is doubtful, therefore, whether the separate administration of acid in water during the meal would accomplish the purpose intended, that is, acidification of the whole stomach contents.

The selection of milk and eggs as a vehicle was made, First, in order to insure acidity in the presence of lime and casein. Secondly, milk is known to absorb large quantities of hydrochloric acid and its acidification previous to introduction must spare whatever there may be of acid secreted in the stomach. Thirdly, hydrochloric acid has a marked solvent action on casein at body temperature.[7]

All patients take two of the whole number of eggs prescribed daily in the milk-egg-acid mixture at the dispensary. The remainder are taken at home immediately after meals as heretofore. Weight gaining is insisted upon in all cases until in the judgment of the physician the total amount gained is sufficient. This weight is then maintained. Most patients who have been under treatment a long time are forbidden to increase their weight because the maximum amount has been reached. Long experience has taught that patients who fail to gain, unless undergoing exacerbations, are either disobedient or too poor to provide proper food. Such are dismissed. As has been stated so often before by the

writer, the systematic employment of cathartics is necessary to insure continuous gain in weight.

After the results which followed the use of dilute hydrochloric acid were observed, ground chicken bone was again administered. It was thought that the failure to obtain results in the first trial might have been due to imperfect peptic action because of lack of sufficient acid in the gastric secretion. No results followed the second trial. Another method of administering extra amounts of lime phosphate tried was to dissolve one grain of precipitated lime phosphate (U.S.D.) in each drachm of dilute hydrochloric acid before its addition to the milk-egg-mixture. No results followed this experiment.

The final method used to hasten the development and increase the amount of plastic effusion, is to give each patient an extra amount of milk without the addition of eggs, to which dilute hydrochloric acid in the proportion of four drachms to the quart is added. This extra milk is prepared at the dispensary, taken home by the patients, and drunk during the day. As a rule men take one quart and women one pint of extra milk. This method has proved entirely successful.

The administration of acid caused such decided general improvement, ascribed to a more complete digestion and, therefore, greater absorption of all food constituents, that the question arose, cannot the quantity of food be further reduced without checking the healing process? This question was the more reasonable because the necessary daily amount of lime phosphate would presumably be supplied by a much smaller number of eggs, particularly. As everyone knows the consumption of raw eggs is a great burden for most patients, and any relief in this direction would both increase the comfort and reduce the cost of treatment. To answer this question the daily quantity of all food (with the exception of milk which at the time of this experiment was one quart daily) was reduced. The maximum number of eggs prescribed in addition to those taken at the dispensary, for men was six, for women, three. The dose of emulsion was reduced one-half and patients were told to eat as much or little of other foods as desired. With few exceptions weight gaining ceased. The large majority lost weight. The most striking effect was observed in connection wtih the lung lesion. All progress toward healing apparently ceased, and this was more convincingly manifest after the experiment was abandoned and patients were again made to gain weight. This experiment, however, was most unsatisfactory. It is impossible to determine accurately the daily intake of all food in dispensary patients because the statements of the patients themselves are the only source of information. Again, among patients who have been receiving a certain quantity of food for a considerable time the processes of metabolism have adjusted themselves to this quantity and the administration of a less amount, even though ample for their needs, will result in loss of weight until metabolism has adjusted itself to the new order of things. The tendency of the body is toward nitrogenous equilibrium. It is evident, therefore, that information regarding the minimum quantity of food required must be obtained from observation of new patients at the dispensary and patients undergoing rest treatment when the daily intake may be absolutely controlled.

Six patients at the dispensary and two patients at rest have so far been observed. Of the dispensary patients three are women. The women receive one pint of extra milk and three extra eggs daily. The men one quart of extra milk and three extra eggs daily. All receive full doses of emulsion. Gain in weight has been continuous and all have developed plastic effusion. More impressive results have been observed in the treatment of patients at rest. Two cases, a woman and a man. The small number of patients who received rest treatment is due to the fact that there are no beds in connection with the dispensary and the patients are too poor to provide reatment in a private hospital.

The history of the woman (case 135) is briefly as follows: Patient under treatment at dispensary from October 24, 1908, to February 15, 1909, when she was operated upon for adenoids and enlarged tonsils. Ether was employed as the anesthetic. Up to the time of operation her progress had been satisfactory. Original weight 101 pounds, weight at time of operation 113 pounds. Immediately following the operation her disease became acute; temperature higher, pulse and respiration quickened, cough increased and much prostration. Visits to the dispensary discontinued and patient confined to house. Examination disclosed spots of consolidation in both lungs increasing in size and number as time passed until the diagnosis of acute pulmonary tuberculosis was made clear. After some delay patient was transferred, April 9, from her boarding house to a private hospital. Weight 99 pounds, afternoon temperature 103.3°, pulse 110, respirations 24, some cyanosis. After entering the hospital the temperature, pulse, and respiration were recorded four times a day until her death, early in August. The following is the condensed record: During April—Highest temperature 103.6°, lowest 99.6°; average morning temperature for the month 100.6°, afternoon 102.3°. Pulse, most rapid 130; daily average 115. Respirations, most rapid 30; daily average 26. May—Highest temperature 102.8°, lowest 99.8°. Average morning temperature for month 100.5°, afternoon 102.6°. Pulse, most rapid 140; daily average 126. Respirations, most rapid 38; daily average 28. June—Highest temperature 103.6°, lowest 100.6°. Average morning temperature for the month 101.2°, afternoon 102.9°. Pulse, most rapid 148; daily average 140. Respirations, most rapid 48; daily average 41. July—Highest temperature 103°, lowest 99.6°. Average morning temperature for the month 101.2°, afternoon 102.4°. Pulse, most rapid 150; daily average 140. Respirations, must rapid 52; daily average 40. Signs of renewed plastic effusion appeared early, were very marked and extended practically over the whole surface of both lungs. During the last month of illness dyspnea and cyanosis were extreme, and attacks of coughing often produced such distress as to suggest impending suffocation. Autopsy not only revealed a marked increase everywhere in fibrous tissue in the lungs, which explained the dyspnea, but in addition a mass of enlarged tuberculous bronchial glands which lay upon the arch of the aorta and apparently occluded this vessel to some extent. This mass was firmly adherent to surrounding structures. Another mass of enlarged glands and inflammatory tissue was found in the median line, just beneath the sternum, at the level of the first and second ribs. Because of their position and gradual enlargement, these glands must have been a factor in causing the persistent and increasing rapidity of the heart's action. This patient consumed daily: Milk, 80 ounces; rare meat, 3 ounces; bread, 6 ounces; butter, 2¼ ounces;

emulsion of mixed fats (42 per cent. fat), 4 ounces. Milk was administered in ten feedings. One drachm of dilute hydrochloric acid was mixed with the milk at each feeding. Meat, bread, and butter in three feedings; emulsion in two feedings. From April 12 to July 25, nothing was added to or subtracted from the diet, and the quantities remained the same throughout this period. July 25 the quantities were reduced because of the distress in breathing and great prostration. Patient was weighed daily. The gain in weight was almost continuous. Weight April 9, 99 pounds; weight July 25, 118¼ pounds.

Second case. The daily amount of food was still further reduced in this case and the results in weight gaining equally gratifying. Charles H., 21 years, U. S., electrician. Began treatment at dispensary May 17, 1909. This patient's lung lesion was not very extensive, though both lungs were involved. His evening temperature, however, was very irregular. Remaining in the neighborhood of 99° or 100° for a time, it would rise to 101° and 102°, and after he stopped work and rested, again subside. This was repeated a number of times, until it became evident he would be obliged to give up both his work and treatment at the dispensary. Hospital treatment was then offered, and he began rest treatment September 1. Total gain while under treatment at dispensary, 5¼ pounds. Weight, September 1, 134½ pounds. Evening temperature 99°, pulse 84. During the first three weeks the evening temperature twice reached 101°, but for most of this time and subsequently ranged between 99° and 100°. Morning temperature, usually subnormal. Highest pulse under 100. This patient received daily: Milk 64 ounces; rare meat, 3 ounces; bread, 6 ounces; butter, 1½ ounces; emulsion of mixed fats (42 per cent. fat), 4 ounces. Weight at beginning of rest treatment 134½ pounds. Weight at the end of six weeks 141½ pounds. This patient has not yet completed rest treatment.

From the standpoint of treatment cases of pulmonary tuberculosis may be divided into two classes, viz., (1) those who require rest strictly, and (2) those who are able to move about without harm. This difference in management is caused by the state of activity of the disease and not by the extent of the lesion. Patients with uncomplicated pulmonary tuberculosis are admitted for treatment at the dispensary in any stage of the disease, whose evening temperature is below 101° and who are clearly not too weak to make the journey from their homes, twice daily; who can provide proper food, clothing, and shelter, and who live within reasonable distance. When other symptoms are favorable patients whose evening temperature is 101° or more are accepted provisionally, because it has occasionally been found that, after one or two weeks of treatment, the temperature falls and remains in the neighborhood of 100°. An evening temperature of 100° and 100½° is not a bar to treatment. It is not meant to imply that this is desirable. It is mentioned as a circumstance arising from the necessities of this work.

But one patient with laryngeal tuberculosis in the stage of ulceration has been treated since the use of hydrochloric acid. This patient had to abandon the treatment because the acid mixture caused so much distress in swallowing. Several cases of this kind were treated with rennet-clotted milk, before the employment of hydrochloric acid, without noticeable benefit.

No patient is admitted whose sputum does not show tubercle bacilli. It frequently happens that the first examinations do not discover this bacillus though the lung lesion is marked. In such cases applicants are kept under observation for several weeks and repeated examinations made before they are refused admission. A number of these patients appear in the table.

Patients are considered apparently cured when physical signs of disease are no longer heard and tubercle bacilli have disappeared from the sputum. At first three consecutive examinations of sputum one month apart, which failed to show the presence of tubercle bacilli, were considered sufficient. Latterly, six consecutive examinations, two weeks apart, are required.

The most satisfactory manner of reporting results of treatment is to give a detailed description and history of every case treated. Lack of space prevents the adoption of this plan here. I have, however, prepared the accompanying table which shows the disposition of every patient who has come under observation since September 12, 1906, the beginning of the experiment. This table also enables those who may possibly prefer a different method of estimating results to do so.

The majority of the patients are working people and continue to work while under treatment. The dispensary hours are arranged with this end especially in view. It frequently happens that patients are admitted who some time before have been told that they have consumption and that they must give up their work and go to the country. No specific instructions have been given for their guidance while away, and very often if they leave the city they do not consult a physician while absent. At best these patients can afford to be away but a few weeks. The one part of the advice which they faithfully follow, whether they leave the city or not, is to give up their employment. In consequence they are being supported by their family or friends. This occurs most often in young unmarried men. These patients are made to go to work.

Rennet-clotted milk was first administered September 12, 1906, the use of hydrochloric acid was begun November 25, 1907, the method of mixing hydrochloric acid, milk, and eggs was begun July 21, 1908. The results here reported date from the first employment of rennet-clotted milk because the subsequent changes in no way alter the original purpose in clotting milk, viz., the certain combination of lime and casein.

Results

Patients under treatment September 12, 1906	29	
Patients admitted since	108	
		137
Patients whose sputum failed to show tubercle bacilli	22	
Patients who remained less than three months	33	
Patients who stopped coming, were dismissed, or developed complications which prevented further treatment	35	
		90
Balance		47

Of this number, 22 are apparently cured or 46.80 per cent.*
Of this number, 25 are still under treatment or 53.20 per cent.

It seems to the writer that the results so far obtained give sufficient promise of an improvement in the treatment of the tuberculous in the home climate to warrant their publication. The experiment is not

*One case (Case No. 1) of fibroid phthisis is included in this number of apparent cures of tuberculosis. Tubercle bacilli were present in this man's sputum when he began treatment. Later, after observing his marked improvement, his sputum was again examined, and repeated examinations failed to discover tubercle bacilli. He still shows marked signs of fibroid phthisis.

yet completed. There are twenty-five of the original number of patients still under treatment. Further reports will, therefore, be made until the work is finished.

As might be expected, the longer the experiment lasts the greater the interval of time between the apparent cures. So far as physical examination gives evidence this is not because of the greater extent of lesion in those still under treatment. The most that can be said is that their disease is either more unyielding, or of greater extent than can be determined by present methods of examination.

These patients and results are classified* as follows:

Class	No.	Per Cent.	Apparently Cured	
			No.	Per Cent.
Incipient	0	0	0	0
Mod advanced	34	72.3	15	44.1
Far advanced	13	27.6	7	53.8

Thirty-five patients discontinued treatment after three months for the following reasons, so far as could be learned:

Stopped without explanation			6†
Moved from city			2
Unable to provide proper food			6
Complications	Cerebral tuberculosis	1 (died)	
	Tuberculous mesenteric glands	1 "	
	Tuberculous arthritis	1	
	Laryngitis, ulcerative	1 (died)	
	Chronic nephritis	1 "	
	Acute pulmonary tuberculosis	1 "	
	Appendicitis, operation	1 "	
		—	7
Exacerbations necessitating prolonged rest			5
Dismissed for disobedience			7
Dismissed for drunkenness			2‡

The following is a statement of the complications which developed or came to notice after treatment was begun, in those patients who subsequently were apparently cured.

Case 1.—Appendicitis. Operation.

Case 2.—Subacute arthritis left elbow and right knee.

Case 13.—Vertebral caries. Small angular kyphosis 9th dorsal vertebra. Cold abscess right costochondral junction under nipple. Suppuration left and right epididymis. Spinal brace applied Oct. 18, 1906.

Case 19.—Carcinoma left breast. Operation Oct. 27, 1908. Surgeon writes that patient "had an exceedingly malignant carcinoma of the breast. I did a complete Halsted operation and she made a prompt recovery. The growth, however, was very cellular and full of mitotic figures which would seem to indicate a high degree of malignancy."

Case 21.—Ischiorectal abscess. Healed.

Case 29.—Scarlet fever, March, 1907. Recovery without complications.

Case 58.—Acute nephritis.

Case 74.—Ischiorectal abscess. Healed.

As will be seen on consulting the table, sufficient time has elapsed to report the ultmate results upon twelve of the apparent cures.

The following table (page 895) shows the result of treatment and the disposition of every patient who has come under observations since the beginning of the experiment:

Report of Reexamination of Patients Two Years or More After Apparent Cure.

Case No.	Date of Re-examination	Condition of Lungs	Present Weight	Tubercle Bacilli in Sputum*	General Health	Present Occupation	Remarks
15	May 7, 1909	No abnormal signs	145½	Absent..	Good....	Foreman.....	Ischiorectal abscess September, 1907. Healed.
2	May 29, "	Signs of disease...	141¼	Present..	Fair.....	Mechanic'l jeweler	Joints occasionally enlarged and give pain.
57	June 10, "	No abnormal signs	139¼	Absent..	Good....	Housewife.....	
3	June 23, "	No abnormal signs	182	Absent..	Good....	Clerk.....	
29	June 20, "	No abnormal signs	96	Absent..	Good....	Shop girl.....	
24	June 30, "	No abnormal signs	137	Absent..	Good....	Housewife.....	Delivered of baby Nov. 8, 1908. Weight of baby at birth, 9 pounds. Nursed baby one month, part feeding, 3 months. Two teeth at six months. Weight at eighth month (July 8) 23 pounds. Perfectly healthy. Third child. First child, empyema when five years old. Operation. Came under writer's care end of 5 months, sinus discharging. Entirely healed end of thirteen months. Present condition, no cough, no signs of disease. Present weight (seven years old) 54 pounds. Second child died of tuberculous meningitis at the age of twenty months.
33	June 30, "	No abnormal signs	105	Absent..	Good....	Outdoor salesman	
13	Aug. 16, "	No abnormal signs	175½	Absent..	Good....	Wood carver.....	Still wears spinal brace. Says there are no symptoms referable to lungs, spine or testicles. Scars in scrotum have remained healed since Nov., 1908, when all discharge ceased.
88	Oct. 1, "	Uncertain signs...	134½	Absent..	Good ..	Housewife.....	Married Mar. 8, 1908. Ischiorectal abscess Aug., 1909. Incised after one week. Still discharging.
58	Oct. 1, "	Signs of disease...	116	Present..	Fair ..	Clerk.....	
26	Oct. 1, "	No abnormal signs	150	Absent..	Good....	Housewife.....	
37	Oct. 13, "	No abnormal signs	197	Absent..	Good....	Lawyer.....	

* Sputum examined each day for three successive days.

†One of these patients disappeared after having two specimens of sputum (counted as one examination) free of tubercle bacilli.

‡Both these patients were dismissed after having one examination of sputum marked free of tubercle bacilli.

Rules of Health.—The Department of Health of the city of Chicago has issued the following rules of health to prevent pneumonia: 1. Avoid poorly ventilated and foul smoking cars. 2. Keep your bedroom windows open at night. 3. Don't overeat. This is a particularly dangerous practice in winter time. 4. Avoid overindulgence in alcoholic drinks. 5. Don't go into the cold air in an overheated condition. 6. Don't be a "draught crank." You need all the pure air you can get. If you wouldn't coddle yourself so much you would get purer air to breathe and your chances of avoiding pneumonia would be much better.

IS THERE A VENEREAL PERIL FOR US?*

By JOHN VAN RENSSELAER HOFF, A.M., M.D., LL.D.,

COLONEL, MEDICAL CORPS, U. S. ARMY.

COINCIDENTLY with the discovery of a "new world" the physicians of Europe observed and described what they regarded as a new disease, syphilis,† and because many believed that the infection was brought back by the sailors of the various exploratory expeditions westward, it was colloquially known as the "American disease." Was this prophetic?

Of course, we now know that syphilis existed among the older peoples long before the fifteenth century, and indeed evidences of this disease have been observed in the bones of prehistoric skeletons. Confined to no geographical entity, its habitat today embraces all places and nations, and its demands are so compelling that they seem to threaten the entire human race.

Twenty years ago a distinguished syphilographer wrote: "In the United States of America syphilis may be recognized in every hospital and in the practice of almost every physician. It is fortunately, however, much more common in the large cities, the rural populations escaping to a happy extent."

Based upon the official medical records of our military forces, probably the only accurate vital statistics of venereal diseases available, are we justified in hoping that this happy exemption will continue among the rural populations even? If so, it can only be through united effort, such as is now making for the control of tuberculosis. Shall such effort be made, and how?

*Presented to the Washington meeting of the Association of Military Surgeons, October 5-8, 1909.

†Of the three distinct affections, syphilis, gonorrhea, and chancroid, known as venereal diseases, little consideration will be given here to chancroid, a local infection, and unimportant to the particular subject of this paper. It will be recalled, however, that the medical statistics of the Civil War and of our army to a much later date included chancroid with syphilis. Based upon recent statistics, I have estimated the rate as one-half for each of these.

By reference to the Medical Statistics of the Provost Marshall General's Office, Vol. I., Chapter II., it will be observed that of the 334,321 drafted men examined and recorded in 1863-64, 8 per thousand were rejected on account of constitutional syphilis.[1] This, of course, is not an absolute indication of the actual number of syphilitics among those examined, but may be accepted as a fair index of the number in the later stages of the disease, for it is not to be presumed that many drafted men would conceal a condition exempting them from military service. This might be so with the recruit, but not the conscript.

Just how many of the men above referred to, other than those rejected, had had syphilis at any time is not recorded, so we must turn to the records of the Surgeon General's Office for information as to the prevalence of the disease in the army, and inferentially in the country, during the civil war and subsequently. I venture to quote somewhat *in extenso* from the medical records of that period.[2]

"Venereal diseases were associated with intemperance in the conditions which favored their causation. Hence they were more frequent at the beginning and the close of the war than during its progress, and among troops stationed in the vicinity of cities than among those on active service. Elevations of the lines of prevalence during the continuance of the war correspond with the accession of fresh levies or the return of furloughed veterans. Among the white troops 73,382 cases of syphilis[3] were reported, and 109,397 cases of gonorrhea and gonorrheal orchitis, giving a total of 82 cases of venereal disease annually per thousand men"—a rate for syphilis of approximately 33 per thousand per annum, probably 16.5 of this rate being chancroid.

It is interesting to observe that the rate for colored troops then was 33.8 for syphilis, including chancroid, and 43.9 for gonorrhea.

For eighteen years immediately preceding the Civil War the rate per annum for all venereal diseases in our army was 87.86 per thousand, and the

ten years subsequent, 87.62[4] (white troops). From 1876 to 1895, inclusive, the average rate was 82.98, decreasing from 107.6 in 1876 to 73.7 in 1895. For the decennial periods between 1868 and 1897, the average annual rate for syphilis only was 67.20, 36.45, and 15.63, respectively. This would indicate that at that time syphilis, including chancroid, caused approximately half of the total disability due to venereal diseases. There was, however, a steady decrease in the rate for syphilis from 105 (52.5 excluding chancroid) per thousand in 1868 to 12 in 1897. On the other hand, the rate for gonorrhea, though decreasing up to 1885, constantly increased thereafter, it being 37.76 in 1885 and 56.21 in 1897, the last named year showing nearly five times as many cases of gonorrhea as of syphilis.

With the increase of the army in 1898 the rates for venereal disease advanced, in 1899, to 128.59 for white and 195.92 for colored troops, the proportion of syphilis being for the former 13.39 to 78.16 of gonorrhea and 37.04 of chancroid and for the latter 22.43 to 109.82 to 63.67.

In 1900 the Surgeon General reported a rate of 133.97, the proportion of syphilis being 15.83 to gonorrhea 78.69.

In 1901[5] "in the army as a whole with a mean strength of 92,491 men there were reported 13,911 cases of venereal disease, equivalent to an admission rate of 150.41 cases per thousand of strength," syphilis being 19.15 to gonorrhea 93.90.

Regarding venereal diseases in 1902 the Surgeon General wrote:[6] "The steadily increasing prevalence of venereal disease is the most discouraging feature in the sick report of the army. During 1902 13,000 admissions were from this cause alone, equivalent to a rate of 160.94 per thousand," syphilis being 22.37 to gonorrhea 106.58.

The admission rate in 1903 was 151.48; syphilis 23.42 to gonorrhea 96.14.

For 1904 the Surgeon General reported:[7] "A considerable increase was noted in the figures for venereal diseases in the troops in the Philippines service over those of the preceding year. The proportions are also much higher than those recorded for the troops in the United States proper, the relative admission rates being 297.42 and 163.42, respectively." The average rate for the entire army was 188.34; syphilis 33.98 to gonorrhea 120.97.

The admission rate for venereal diseases in 1905 was 198.93; syphilis 34.34 to gonorrhea 131.30.

In 1906 the rate was 190.46; syphilis 28.60 to gonorrhea 124.65.

In 1907 the rate was 196.62; syphilis 28.92 to gonorrhea 123.30, and in 1908, rate, 194.15; syphilis 26.40 to gonorrhea 135.56.

RECAPITULATION

Admission Rate for Venereal Diseases, Entire Army

Year	Venereal Rate	Syphilis	Gonorrhea	Chancroid
1899	133.00	13.98	80.23	38.79
1900	133.97	15.83	78.69	39.45
1901	150.41	19.15	93.90	37.36
1902	160.94	22.37	106.58	31.99
1903	151.48	23.42	96.14	31.92
1904	188.34	33.98	120.97	33.39
1905	198.93	34.34	131.30	33.29
1906	190.46	28.60	124.65	37.21
1907	196.62	28.92	123.30	44.40
1908	194.15	26.40	135.56	32.19
Total	1,698.30	246.99	1,091.32	359.99
Average	169.83	24.70	109.13	36.00

Admission Rate for Venereal Diseases, Army in United States

Year	Venereal Rate	Syphilis	Gonorrhea	Chancroid
1899	127.28	13.49	87.29	26.57
1900	133.97	19.62	102.42	33.35
1901	149.96	19.35	104.21	26.40
1902	161.14	23.03	108.54	29.57
1903	135.84	23.64	84.09	28.11
1904	163.42	28.47	107.05	27.90
1905	178.72	30.02	118.31	30.39
1906	158.91	27.28	105.21	26.41
1907	167.82	25.36	107.68	34.78
Total	1,377.06	210.26	924.80	263.48
Average	153.01	23.36	102.78	29.28

Note.—This table does not include the year 1908, figures for which were not available when it was compiled.

It would appear from the foregoing statistics that compared with those immediately before, during and after the Civil War the rate of admission for all venereal diseases increased from an average of 85.11 to a rate of 194.15, syphilis increasing from an average of approximately 19 (37.82 including chancroid) to 26.40 per thousand, while gonorrhea increased from 47.99 to 135.56. It will be observed, however, that during the last decennium there was a steady increase from the year 1897, with the lowest record of 12 cases of syphilis per thousand, up to 1905, with a maximum record of 34.34, since which year there has been a slight decrease. On the other hand, the rate for gonorrhea advanced from 56.21 in 1897 to 131.30 in 1905, though it fell to 123.30 two years later, but last year it advanced to 135.56, the highest recorded rate.

While the highest rate for syphilis recently attained, that for 1905, is much greater than that during the Civil War, the rate is now steadily decreasing, and it is reasonable to assume that it will be quite possible to regain the standard of 1897 even though[8] "troops quartered among a foreign but not hostile population almost invariably suffer worse in respect to venereal diseases than do those at home."

With this promising outlook as to syphilis in our army it is fair to assume that this disease is not much more widely disseminated proportionately among our military resources, the eleven million male citizens of military age, than it was in the "sixties," and that in case of conscription the relative loss[9] would be no greater now, viz., 8 per thousand.

It would be quite otherwise with gonorrhea and its sequellæ in which the rate has greatly increased. Seven per thousand of drafted men were rejected on this account in 1863-4, when the army rate per annum was 50, and it would not be unreasonable to assume that twice this number would fail us with an army rate of 135.

It may be asked, is there any legitimate basis of comparison between civil and military vital statistics? Perhaps more as to venereal diseases than any others, for these pertain chiefly to youth and early manhood, the soldier age. Von Tophy writes:[10] "The relative venereal morbidity in armies bears a close relationship to the prevalence of this class of diseases among the civilians in the district in which they are quartered."

Taking the average annual rate of syphilis in our army for the current century as the probable rate for those of military age, 18 to 45 years, the number of syphilitic men in the United States last year was 271,700. Assuming that an equal number from the previous year were undergoing cure, and allowing for those previously uncured, it is not

unreasonable to conclude that there are today over a half million syphilitic men in the United States.

This does not seem an excessive estimate if that of Lemoix[11] be correct, who says of syphilis, "In Paris among 100 men at least 13 to 16 infected individuals may be counted."

Adding to the 500,000 syphilitic men, 1,500,000 with gonorrhea, and making a reasonable allowance for chancroid, we may safely estimate that at least two million men suffered from venereal diseases in the United States last year. How many of the other sex likewise suffered I would not dare even to surmise.

What loss to the country is involved in venereal morbidity?

In the military service it is a large item equivalent in our army to the services of an entire regiment every day.[12] "The average number of days treatment for gonorrheal cases was 21.96, for syphilitic cases 40.27." It is not believed that the number of days lost by civilians is so great as in the army, where cases of venereal disease are usually isolated and treated in hospital until active symptoms subside.

But even if we assume that the average non-efficiency of the civilian, from venereal, is half that of the soldier, say 10 days for gonorrhea and 20 for syphilis, the time lost last year on account of venereal was approximately twenty-five million days. The economic value to the country of these lost days is worth considering. It represents the work of an army of nearly 68,500 men for a year—about what we actually have in the service today.

Our people, apparently, have not up to the present time regarded venereal diseases seriously. Even many physicians are disinclined to believe that syphilis has much influence on mortality, while gonorrhea has been looked upon as a joke. Metchnikoff says,[13] "It is quite true that syphilis by itself is not a fatal disease * * * yet, in spite of this, syphilis is one of the most important causes in shortening human life and in bringing about mortal diseases." His discussion of Professor Runeberg's insurance statistics[14] is so pertinent and interesting that I should like to quote it in full did space permit. Suffice it to say that Runeberg showed that 15 per cent. of deaths among members of the Insurance Society of Kaleva was traceable to syphilis. "Among the other diseases that caused the death of insured persons stands foremost tuberculosis, with a mortality of 21 per cent., while pneumonia follows as third with 10 per cent. Thus we receive conformation of the general opinion that, next to tuberculosis, syphilis plays the most important rôle in the death rate of persons whose lives have been insured, *i. e.* of the most vigorous part of the population."

What may be said of gonorrhea? Old as the human race its records have come down to us through history and its onward march has left in its wake blind, halt, maimed, and sexless multitudes. As indicated in this paper, it is to-day contributing no little to the non-efficiency of our men at the most productive age, thousands of women are direct and indirect sufferers from this infection, and I have no doubt it is a considerable, though hidden, factor in the mortality of the race.

From the foregoing it is believed we are justified in answering that there is indeed a venereal peril for the United States, and it behooves us to realize it and take immediate steps to abate it.

The prophylaxis of venereal diseases, while strictly speaking, no part of our subject, but which I may be pardoned for referring to, is a matter that has demanded and received the ablest consideration; but unfortunately no universal consensus of opinion has been reached regarding it.

Metchnikoff believes that until a better method can be found the regulation of prostitutes is the least of two evils. But apparently the legal recognition of the causes and regulation of the conditions which result from the so-called "social evil" are not approved by our people and we must look elsewhere for means of prevention. May we not take advantage of the increasing acceptance of instruction in hygiene, as part of public education, to teach the people something of the meaning and dangers of venereal diseases? Truly; but even this is not without danger, for ignorance of the nature of these infections is by no means the sole cause of their existence. Still, I believe the good done would far outweigh the evil.

Few of our people appreciate the considerable number of non-venereal, innocent cases of syphilis there are. Speaking of this, Tarnovsky says,[15] "Rural syphilis in Russia is first and foremost, a syphilis of the innocent, and spreads far more generally throughout the mass of the people without distinctions of age or sex. The infant soon after its birth is often infected by a kiss from one of its parents who has contracted the infection. The grand parents may in the same manner acquire the disease by eating from the same vessels or by drinking out of the same glasses," etc. Surely education would keep us from such terrible conditions.

Then, too, the number of cases of innocent gonorrhea is by no means small, but might be smaller, did the people generally but know that the gonorrheal discharge is the infecting medium, and if brought in contact with the eye, for example, will quite likely destroy its sight.

Extensive experiments are making to discover vaccines to immunize against venereal diseases, especially syphilis, and it is reasonable to assume that presently immunizers will be found for these affections. When that happens, when all our unfortunate prostitutes, who, like the poor, will probably always be with us, can protect themselves by vaccination against the ravages of venereal infection, most of them will do so and cease to be transmitters of these diseases. Then these dreadful infections will in due time become negligible. In the meantime it is exceedingly important that we should use such means of prophylaxis as are now available.

On January 25, 1909, the Surgeon-General of the Army issued the following:

MEMORANDUM.

"The attention of all medical officers is invited to the importance of making vigorous and sustained efforts to prevent the spread of venereal diseases in the army.

"Reports since the Spanish-American War show a steady and progressive increase in this class of diseases so that the admission rate which was 84.59 per thousand in 1897 has now reached the enormous figure of 196.62 per thousand. These figures are out of all proportion to those which obtain in the European armies. The rates for the latter being according to the latest obtainable information: For the British army, 97.04; Austro-Hungarian, 60; French, 29.08; Prussian, 19.08; Bavarian, 14.06.

"Among the measures which have been found

most successful in other services in controlling this disease have been the following:

"(1) The organization of soldiers' clubs, canteens, etc., where enlisted men can find amusement and recreation sufficiently attractive to keep them at home and away from vile resorts.

"(2) The formation of temperance associations among the enlisted men; the association of intemperance and venereal indulgence being well understood.

"(3) The early detection of all cases of venereal diseases by periodical physical examination of the men stripped.

"(4) Keeping all cases of venereal disease under continuous observation and treatment until they are cured. For this purpose, venereal registers are kept, and a case once on the books is never lost sight of until cured. Should a man be transferred, while under treatment, to another post or station, his venereal history goes with him.

"(5) Instruction of the men by lectures, and by informal advice whenever the opportunity offers as to the nature of venereal diseases, the extent of their prevalence among prostitutes and the grave peril not only to those who contract them, but to their families and posterity. They should also be taught that sexual intercourse is not necessary to good health and the highest degree of mental and physical vigor.

"(6) Approved measures of personal prophylaxis of those who will, contrary to advice, expose themselves to venereal infection. All the principal European armies with the exception of that of Great Britain have officially authorized or directed the use of such prophylactic measures, and a considerable degree of success has attended their use. In some of the Austrian garrisons this system is said to have effected a decrease of 62 per cent. in the cases of venereal disease. In the German army equally good results have been reported. The general procedure in all the armies is about the same, though there are slight differences in the details, especially in regard to the particular antiseptic employed.

"In the first place, medical officers explain to the men the necessity for the utmost cleanliness in sexual intercourse, and thorough ablution immediately afterward, followed by the act of urination to wash out the urethra. A specified place in each barrack, usually one of the wash rooms, has special arrangements provided for prompt ablution and washing with a disinfectant, such as 1-1000 solution of bichloride of mercury, immediately upon returning to barracks. For the prevention of gonorrhea, a few drops of 1 per cent. solution of nitrate of silver, or a 20 per cent. solution of argyrol, are injected into the urethra, or it is washed out with a warm 1-5000 solution of permanganate of potash. For the prevention of syphilis, a 30 per cent. calomel ointment is used, which is rubbed into the penis after the employment of the injection. Glass medicine droppers are used to give the injection of the silver preparations, and are kept for this purpose in an antiseptic solution and boiled after each use. The soldier is instructed to enter in a register which is kept for the purpose, his name and the date and hour of the use of the preventative, and the number of hours which have elapsed since sexual intercourse. It is to be explained to him that promptness in the use of preventatives is of the first importance.

"Geo. H. Torney, Surgeon-General."

It must not be assumed that no previous effort had been made to control the ravages of venereal diseases in the army, for such is not the case. In our dependencies, where non-efficiency from these causes is most marked, there have been determined efforts at control, and at home as well.[16] In the Department of the Lakes in February, 1905, the then Chief Surgeon, Colonel P. F. Harvey, Medical Corps, called attention to the prevalence of venereal diseases, suggested means of prophylaxis, and directed that the plan followed by Major H. I. Raymond, Medical Corps, Surgeon, Columbus Barracks, Ohio, be employed, etc. It cannot be said that the results here have equaled legitimate expectation, due largely to causes which made a material decrease in venereal almost impossible. We must have a simultaneous, uniform, and effectively applied system throughout the entire army if good results are to be obtained.

The memorandum from the Surgeon General is a timely word of warning regarding venereal diseases, addressed to the whole army from the War Department, and cannot fail of good results in due time if the army will but heed it. This memorandum was promulgated in the Department of the Lakes by the Commanding General, March 9, 1909, an advance copy thereof having been sent to the post surgeons February 4, 1909.

As shown by the subjoined table,[17] no marked changes in the admission rate for venereal during the last six months since the memorandum was promulgated, from that for the same period in 1908 are observed. Nor could a different result be expected under existing conditions.

The admission rate for the Department of the Lakes for the last calendar year was considerably in excess of the average for the whole army. This was due to several causes—the Maneuver Camp at Fort Benjamin Harrison, from which a large number of venereal cases were admitted to sick report and charged against that post, the arrival of a regiment from the Philippines, and the temporary assignment of some 700 recruits to the regular garrisons, etc.

This year but one post, Fort Thomas, has the same garrison, practically, it had the whole (10 months) of last year, and it shows a decrease of venereal to the extent of 20 per thousand, though it leads the Department in non-efficiency from this cause.

Venereal Admission Rate per Thousand, Department of the Lakes for Six Months, March to August, Inclusive

Stations	1908				1909			
	Venereal Ulcer	Gonorrhœa	Syphilis	Total	Venereal Ulcer	Gonorrhœa	Syphilis	Total

* Post not garrisoned until May, 1908.

† Under venereal ulcer (Dept. 1908) are included cases shown in record as "other venereal diseases" amounting to a rate of 25.81.

It is hardly necessary to say here that the solution of the venereal problem in the army is not alone the task of the medical officer, any more than

its solution among civil communities pertains alone to civilian practitioners. It is our duty to keep the proper authority informed of the presence and rate of these diseases, and to quickly cure the subjects or eliminate them from the service. But beyond that we only share equally with all other officers and men, as well, the duty of lessening this terrible cause of non-efficiency, and unless all work together for this result it will not be obtained.

The six suggestions for control of venereal disease offered by the Surgeon General of the Army:

Organization of soldiers' clubs;
Formation of temperance societies;
Early detection of venereal disease;
Keeping of cases under observation and treatment till cured;
Instruction by lectures and advice, and the
Employment of measures of personal prophylaxis,

all demand cooperation if they are to be made effective.

The routine bi-weekly physical inspection of the men should be made to determine among other things, the genital condition. I say among "other things," for it is necessary to the efficacy of the soldier that we should be informed of the state of the skin, the teeth, the feet, and general physical condition as well. Such examinations should not be designated "venereal," for the term is distastful and tends to defeat their object. They must be thorough, and the company commander should accompany the medical officer when they are made.

We study the physical state of our horses with the utmost particularity; is that of our men any less important?

Precept and example will do much, but in spite of these there will remain some whose sexual appetite will not be curbed by moral suasion. Such should and can be protected. The plan of personal prophylaxis suggested by the Surgeon General will be effective only so far as the individual is willing to avail himself of it and does so in time. Many will, but others for various reasons will not. For such the prophylactic package recommended by Colonel Harvey can be employed. This package consists of a vial containing 2 cc. of a solution of protargol 20 parts, glycerin 20 parts, distilled water 60 parts, and a medicine dropper. To make the packet complete a box of calomel ointment, 30 per cent., should be added, or the packet recommended by[18] Passed Assistant Surgeon E. M. Brown, U. S. Navy, would meet the requirements.

Such packets should be obtainable from military hospitals gratuitously, and also by purchase from the post exchange. The latter is important, because I believe the American soldier would be more likely to buy his own prophylactic than to advertise the fact that he was about to place himself in a position where he would require such by going to the hospital for it. The packet conveniently at hand would be more likely to be used immediately after copulation, than the means provided at the barracks, and this could be done privately.

An important addition to the means of control above suggested is sufficient publicity to keep the responsible officer constantly informed of the movement of disease in his own command, and, for the purpose of comparison, in neighboring garrisons. For this there is issued in the Department of the Lakes a monthly statement giving the rates for all classes of sickness at the several posts. This statement is sent out officially through military channels to post commands, and it is believed produces good results, as it is inconceivable that commanders will remain indifferent when "in figures that admit of no denial" the loss in the efficiency of their commands, due to venereal diseases, is constantly thrust upon their attention.

Then, too, there are other means of control which need not be dwelt upon here.

So much for our army. Is there anything that can be done for the people?

We have eliminated regulation as impracticable, we have suggested education as to the dangers of venereal infections.

Vaccination is not yet an established fact, but, until it is, we can use the same means of personal prophylaxis for our people as that employed for our soldiers, and this should be done. Moreover, the knowledge of the means of protection should be as widely promulgated as of the dangers of infection.

We of the United States have a serious peril confronting us, which threatens national venereal infection. Strange to say there are not lacking those who discourage all effort to control venereal disease on the ground that such control encourages vice. Indeed, so strong is this sentiment that our Government does not attempt to protect its citizens against these infections, though it does so against all other infectious diseases.

The sexual instinct is a condition, not a theory, and its demands are not always controllable. Some of our people will act from instinct rather than reason, do what we may to inform them. Could such alone be made to suffer for their immoral practices, we might dismiss the subject, as an economic proposition, without further consideration. Unfortunately this is impossible, consequently every person exposed to the probability of venereal infection should be protected against himself, otherwise he becomes a possible nuisance to the community, threatening the health of the innocent and guilty alike. More than that, threatening generations unborn and the very existence of the race.

"No considerations of a moralizing tendency should be opposed to the prevention of so disastrous a calamity" as universal venereal infection among our people.

HEMOLYSIS AND ITS DIAGNOSTIC SIGNIFICANCE IN CANCER AND TUBERCULOSIS.*

By FRANK SMITHIES, M.D.,
ANN ARBOR, MICHIGAN.

Any procedure, be it technical or otherwise, which contributes something to our knowledge of the cause, prophylaxis, and cure of disease warrants consideration and investigation. This is especially true where the elucidation of problems connected with such widespread affections as cancer and tuberculosis is concerned. Laboratory research, coupled with bedside observation, has been productive of valuable results to the profession and to humanity during the past ten years. The early studies of Bordet and Gengou with respect to certain physical and chemical properties of blood serum gave impetus to what had been a rather haphazard series of investigations. Out of these studies directly or indirectly grew the theory of opsonins, as elaborated by Wright, the precipitin reactions for the identification of blood sera of different species of animals, the serum diagnosis of syphilis, and more recently, the attempts to correlate and interpret certain frequently observed phenomena in blood serum from patients affected with cancer and tuberculosis.

It will be granted that many cases of cancer and tuberculosis are readily diagnosable by ordinary clinical procedures. More or less typical alterations of visible tissues, cachexias, the data derived from physical examination, together with simple and routine laboratory methods often suffice to make one reasonably sure of his ground. It is the common experience, however, that there are instances where only pathological section of tissue, and that in the hands of an expert, gives the definite evidence that we seek. And this is particularly so where the disease focus is situated in a region anatomically difficult of access, as in the mediastinum, the retroperitoneal region, certain parts of the liver, of the kidney, etc. It is in this class of cases that we welcome any diagnostic measure which gives promise of proving practicable and dependable.

The study of blood—both serum and corpuscles—in the attempt to discover features distinct for new growths has been carried on for some years. Ehrlich and a large number of followers studied the corpuscular elements of blood, in the endeavor to prove by certain dyes that malignant disease caused certain morphological alterations. Except for the wealth of information with respect to differential estimations of leucocytes, the phenomena of the affinity of their various parts for divers stains, and the establishment of the fact that the anemia of cancer was but a type of secondary anemia, nothing of great practical worth in the diagnosis of malignant disease was discovered. It naturally followed that the chemistry and the physical properties of the blood serum were next investigated. Variations in the organic components of the serum of different individuals were observed, but these variations were not constant for any given disease, being found in noncancerous patients as well as in those affected with cancer. In 1900, it was shown by Grunbaum[1] and Ascoli[2] that the blood serum in certain diseases, including cancer, agglutinated the blood corpuscles of persons apparently well, but did not agglutinate the corpuscles of the subject from which these red cells were taken. This phenomenon was apparently verified in several diseases. In cancer and malaria, it appeared to occur consistently. It was later proven by the investigations of Donath,[3] Gay,[4] and others, that these reactions had little practical diagnostic value.

The more recent researches have attempted to demonstrate that there exists in the blood serum of patients affected with cancer, certain substance or substances which are capable of causing destruction of the red blood cells of patients not cancerous, and probably, to a certain extent, of the blood cells of the cancer patients themselves. This phenomenon of "hemolysis" was first commented upon by Kelling,[5] who had observed its occurrence when serum from human cancer patients was brought into contact with the red cells of sheep, cows, and chickens. Kelling showed that the blood serum of many cases of cancer destroyed the erythrocytes, whereas serum from normal patients did not. It was shown by Fischel,[6] however, that while these observations held for cancer there were also other diseases, as pernicious anemia, tuberculosis, severe diabetes, etc., the sera from which patients when brought into contact with alien corpuscles exhibited similar characteristics. It did not seem, therefore, that the reaction observed in cancer patients could be considered specific.

Two years ago Weil[7] described a new method of studying hemolysis in disease. His early work was carried on with the blood sera of dogs which had been infected with the type of tumor known as "infectious lymphosarcoma." Weil showed that the salt solution extract of these tumors had little effect upon the red cells unless the tumors had become broken down and necrosed. In this latter event, the salt solution extract caused rapid hemolysis with liberation of blood coloring matter. To guard against the possibility of infection in the necrotic tumor masses being responsible for the phenomenon noted, and also to prove that in the breaking down of tumors—their autolysis—certain poisonous materials were developed, similar necrosis of noncancerous tissue—as in the kidney—was accomplished experimentally and aseptically. It was found that in these necrotic foci there also existed materials which caused destruction of erythrocytes. The blood serum of dogs affected with tumors in the stage of necrosis was next investigated, with the object of determining the possible presence of poisonous materials in the circulation. It was shown that the blood serum of dogs thus affected had a remarkable destructive power when brought into contact with dog's red cells. The blood serum of normal dogs was rarely hemolytic. It was also demonstrated that the red cells of dogs, affected with tumors, possessed more resistence to the destructive affected of cancer-dog serum than did the cells of dogs not so affected. In other words, the erythrocytes of the cancer dogs appeared to possess a certain added resistance—an immunity—to the poisonous effects of the substances circulating in the blood of such dogs. The precise nature of the poisonous material has not as yet been determined. It has been shown, however, by Wade that certain substances can be isolated from necrotic tumors, which, when injected into dogs, are capable of producing interstitial nephritis.

It will be readily appreciated what a short step it was from the study of these so-called "serum-hemolysis reactions" in animals to their investigation in humans. The work has been eagerly taken up in

*Read before the Calhoun County Medical Society, Ceresco, June 1, 1909. From the clinical laboratory of Dr Smithies.

this country, notably by Weil,[8,9] Crile,[10] Wittemore,[11] Blumgarten,[12] Johnstone and Canning,[13] and others.

The early work of Weil,[14, 15] on a series of eighty-two cases showed that with serum of late malignant tumors 56 per cent. produced destruction of the red cells of clinically well patients. Thirty-three per cent. of sera from benign tumor patients as well as 26 per cent. of sera from patients affected with diseases other than cancer were also hemolytic. In Weil's series the blood sera from no normal cases produced destruction of erythrocytes. The investigations of Wittemore revealed that of 109 cases, normal and otherwise, hemolysis occurred in 36 per cent. of the carcinoma cases—all stages—in 50 per cent. of tuberculous patients—all degrees of advancement—in 18 per cent. of patients affected with ailments others than cancer, and in 17 per cent. of normal individuals. Blumgarten reports that 72 per cent. of cancer sera, in his series, produced hemolysis, while the serum of but 10 per cent. of patients affected with disease other than cancer caused destruction of red cells.

The most complete study of the serum reaction in cancer, from the clinical viewpoint, has been made by Crile and his assistants. These workers claim to have developed such perfection in technique that the high percentage of positive reactions in a very large series of cases warrants careful consideration. A total of 591 cases is reported by Crile. Of these, there were 211 normal individuals. In none of the normals was the reaction of hemolysis obtained. Seventy-one cases of pyogenic infection were tested, with hemolysis in about 10 per cent. Of 55 cases with benign tumors, the serum from none was hemolytic. Of 153 cases of cancer—all stages—130 or 85 per cent. produced hemolysis of healthy, human red cells. Of 11 cases of cancer, with clinical recurrence, 100 per cent. maintained persistence of positive reaction. Of 37 cases, postoperative, without clinical recurrence, examined at periods of from three weeks to fifteen years after operation, none exhibited hemolytic properties in their sera. Of 52 cases of tuberculosis, 92 per cent. showed the so-called reaction of "reverse hemolysis," the discussion of which will be attempted later. Crile noted that cancer cases showing no hemolysis were late, inoperable growths; that cancers of the mucous membranes showed more uniform hemolysis than did those in tissues such as the breast; that in cases which had been operated on with no recurrence the hemolytic power of the sera was lost in from twelve to twenty-one days; that in cases where incomplete operation had been performed, the serum never lost its hemolytic power. Crile also observed that if serum be heated to 55° Centigrade, it lost its hemolytic power, while if it were chilled, the hemolytic power was increased. Plasma used shortly after blood had been obtained from the patient was shown to be weak in hemolysins, while that which had stood for twenty-four hours on ice, was very rich in hemolysins. Recently, Johnstone and Canning have reported results which agree in the main with those of Crile and his coworkers. They have, however, noted the presence of the reactions in disease conditions other than cancer.

The results obtained by Crile appear to be at such variance from those reported by other dependable investigators as to excite more than passing interest. Either the improved technique suggested by Crile has been responsible for the apparent reliability of the reaction, or the manifestations of the reaction have been misinterpreted. This applies especially with respect to the cases of tuberculosis giving the so-called "reverse hemolysis." By this is meant that serum of a patient affected with tuberculosis will not hemolyze its own or other human corpuscles, but that the serum from a normal individual will destroy the erythrocytes from a tuberculous individual.

The work outlined in this brief and what must be considered preliminary report, was undertaken for the purpose of satisfying the writer of the practical clinical worth of the hemolytic reactions in cancer and tuberculosis. Added interest was given to the research by the working, in many instances, of the reaction simultaneously with the Wassermann reaction for lues, the positive manifestations of which were in more or less direct contrast to those obtained in the serum test.

It will be recognized, as has been pointed out by many observers, notably Weil and Crile, that there are many difficulties in the performing of the various steps of the reaction. But these difficulties are not greater than those encountered in the estimation of the opsonic index, the manipulations of the Wassermann reaction, or other exact laboratory procedures. The technique is well within the range of men who have had modern bacteriological training. There is sometimes difficulty in getting subjects to submit to the bleeding for the serum, but these can usually be surmounted by tact and patience. In the early part of the work the general principles outlined by Crile were observed; in the latter part of the investigation, these were somewhat modified for the purpose of better adapting the manipulation to practical clinical work. The modification did not appear to alter the results obtained.

The steps in the reaction have been frequently described. Blood is obtained from the subject, either by direct puncture of the arm veins or from the end of the finger, under aseptic conditions. It is necessary to obtain from each patient, blood corpuscles and blood serum in separate containers. In order to obtain the serum, blood is allowed to run directly into sterile test tubes. From forty to sixty drops are usually sufficient. If much serum is required for the purpose of running many sets of controls, then from five to ten cubic centimeters of blood should be obtained. This large amount can best be secured by direct puncture of a superficial arm vein. After obtaining the blood for serum, the test tube is either slanted and placed at once in the ice box, or is at once centrifugalized, and after the serum has thus been mechanically separated, is then placed at icebox temperature for from twelve to twenty-four hours. It is especially requisite that serum be kept at even temperature. If the temperature fluctuates the hemolytic properties of the sera are greatly affected. The red blood cells for the test are obtained by allowing from ten to twenty drops of fresh blood to run into salt-citrate solution or into a tube or flask containing several small glass beads. In the latter event the tube or flask is gently agitated and defibrination accomplished, with prevention of clotting. It has not appeared best to us to prevent clotting in this way. There seem to be several objections. Cells are readily injured by the sharp edges of the beads, and it seems that hemolysis is more readily brought about in them than under conditions where cells are preserved in salt or salt-citrate solution. Defibrination by beads is cumbersome, the cells are sometimes separated from the fibrin shred with considerable difficulty,

and if the shreds are not separated, it is frequently noted that hemolysis is delayed or interfered with on account of cells being entangled within the fibrin network. Before using the corpuscles it is necessary to wash them several times with normal salt solution. Sometimes it is difficult to free the cells from fibrin when glass beads have been used. The bits may seriously interfere with the reaction as a consequence. After washing, the erythrocytes are placed on ice to be used when serum is available.

In the manner above described, blood serum and red cells are obtained from normal individuals, etc. When the components of the reactions have been thus prepared, the test is ready to set up. As before mentioned, it has not appeared necessary to use the triple controls suggested by Crile. It does not appear that there is any greater accuracy in such method than when a few well-manipulated controls are followed. The sources of error are certainly greater. We have in all cases tested each suspected serum with at least two normals, and against cells suspended in normal salt, and against cells and sera in sterile water. With Crile and others we have noted that heating sera above 55° Centigrade prevented hemolysis.

Our procedure in carrying out the test is to add to the several test-tubes successively five or ten drops of a 5 per cent. suspension of normal red cells in normal salt solution, then respectively three to six drops of blood serum from the cancer patient (or other subject), three to six drops of blood serum from the normals, three to six drops of normal salt solution, and three to six drops of sterile water. To the next group are added, respectively, five or ten drops of a 5 per cent. suspension of red cells from the cancer patient (or other subject), and then to the various tubes three to six drops of normal serum, of serum from the suspected individual, of normal salt, and of sterile water. The tubes are then thoroughly agitated. When the smaller portions of each constituent of the reaction are used, the mixing may be best done with capillary pipettes, after the fashion of cell suspension mixing in the working of the opsonic index. After thorough mixing, the tubes are placed in a thermostat at 37° Centigrade for two hours. If the tubes are placed in a vessel containing water in the incubator, it is possible that they may be agitated several times during the period of incubation, without interfering with the progress of the reaction. After incubation, the tubes are removed from the incubator and placed at icebox temperature for twelve hours. They should be shaken once or twice during this period. The tubes are then observed for evidences of hemolysis. This is shown by the pink coloration of the fluid above the cell débris. It is best to have the observations made by someone who knows nothing of the clinical histories of the cases being tested. If reactions are read after twenty-four hours following removal of the tubes from the thermostat, the information derived is dubious, inasmuch as hemolysis may occur in tubes containing no serum. It is rare to secure hemolysis in any tube as complete as that in the control containing sterile water, even though the hemolytic properties of the serum tests are marked.

The results furnishing the basis of this communication are based upon the findings in 85 cases affected with various ailments, as will be seen by reference to Table I. It is impossible here to go into details with respect to each individual tested. Some were very interesting, particularly the cancer cases, the syphilitics, the tuberculous patients, and those subjects affected with non-malignant diseases, but with diseases frequently productive of anemia, as Graves' disease, pernicious and severe secondary anemias, Addison's disease, etc.

Table II.—Summary

Clinical Diagnosis	Cases	Positive	Reaction		
			Negative	Undetermined	Reverse
Cancer	12	7 (58.3%)	3 (25%)	2 (16.66%)	0
Benign tumors	2	0	2 (100%)	0	0
Tuberculosis	15	1 (6.6%)	6 (40%)	6 (40%)	2
Syphilis	12	1 (8.3%)	8 (65%)	3	0
Non-cancerous disease, generally	25	5 (20%)	13 (52%)	6	1
Normal individuals	19	1 (5.3%)	18 (92.7%)	0	0
Total	85	15	50	17	3

It might be of value to say a few words with respect to the reactions in the cancer cases. By positive reaction we mean that the normal red cells to which cancer serum has been added, are destroyed (hemolyzed) more or less completely, while the

cancer patient's red cells to which normal, and frequently cancer serum (as will be seen), has been added are not hemolyzed. The reactions which we have classed as "undetermined" are those where hemolysis was found to be present in both combinations. By the reaction of "reverse hemolysis," it will be recalled we mean that the cells of the suspected patient are hemolyzed by normal, alien serum. Of the malignant tumors, the serum of which we had opportunity of testing, it will be noted that, in the main, serum from moderately advanced and advanced cases reacted well, while recent tumors either caused poorly manifested reaction or none at all. There is one necrotic case noted. The reaction did not appear to be as pronounced as some of the long growing tumors where breaking down was not prominent. This necrotic case was a late carcinoma of the jaw. The cases which did not react at all were one early carcinoma of the prostate, one scirrhus carcinoma of the stomach, and one early malignant tumor of the breast. There were two "undetermined" reactions, namely, a late cancer of the breast and an early cancer of the uterus. There was one case of "reverse hemolysis," a moderately advanced carcinoma of the uterus. At the present state of our knowledge it does not seem proper that we attempt explanation of the variations noted. It might be said that where the cases are marked "undetermined," the hemolysis was invariably more pronounced in the tubes where the action of the cancer patient's serum on the alien cells was being observed. Our percentage of rather more than 58 per cent. positive reactions compares favorably with that of Weil, Wittemore, and Blumgarten, but does not approach the high figures submitted by Crile and Johnstone and Canning. Perhaps were our series larger we should have more encouraging figures to offer.

Sera from two patients affected with benign tumors were tested. In neither were positive reactions obtained. It would seem that this fact is important diagnostically. Given a tumor, the nature of which is in doubt, the obtaining of positive hemolytic reaction might be of value in directing surgical procedures. And this especially when taken in connection with the fact that practically all the well-developed malignant growths in our series gave distinct positive manifestations.

Of the fifteen cases of tuberculosis examined, but two revealed the "reverse hemolysis" first emphasized by Crile. Both these cases had moderately advanced lesions. One case of tuberculosis exhibited direct hemolysis. This was a male, with general genitourinary tract involvement, and beginning changes in both lungs. Six cases of tuberculosis showed negative reaction, and a like number are for fairness recorded as "undetermined." Some of these showed slight hemolysis and might have been called negative by a worker more experienced with the test than the writer.

Of the twelve cases of syphilis, eight or 65 per cent. were negative, while three were classed as "undetermined." In all, the reactions were slightly manifested. One case—a patient with tertiary lesions and grave anemia—exhibited positive reaction.

Of twenty-five patients affected with various more or less serious diseases, selected at random, five or 20 per cent. exhibited positive reaction. It will be granted that in the majority of these the changes were not very marked, but the hemolysis was greater than in the controls, and the evidence is submitted for what it is worth. These cases reacting were respectively, chlorosis, severe secondary anemia, arteriosclerosis with anemia, Graves' disease with anemia and rapid loss of weight, and severe tonsillitis with sloughing of the tonsil and high fever. The reactions in the anemias are extremely interesting, especially with respect to the supposed hemolytic factors entering into the production of such diseases as pernicious anemia. It will be noted that one case of pernicious anemia was tested. It is classed with the "undetermined" reactions. The hemolysis was, however, more marked in the tube containing the patient's serum and the normal corpuscles. Of the twenty-five patients ill, but clinically noncancerous, six were classed as "undetermined." It will be seen that these were respectively severe acne, chronic parenchymatous nephritis, old rheumatic endocarditis, gallstones with jaundice, neurasthenia, and the above-mentioned pernicious anemia. One case of chorea—a young female with anemia—exhibited "reverse hemolysis."

Of the clinically normal individuals—nineteen in number—one gave slight positive reaction, while 92.7 per cent. were negative. We have no explanation to offer for the occurrence of this positive reaction. Similar observations have been made by Wittemore and by Blumgarten. The possibility of an unrecognized infective focus, a previous illness, or an error in technique should be considered.

It would appear, then, from this brief consideration of the work of others and the results we submit, that certain facts are brought forward quite prominently. It seems that the blood serum of the majority of patients affected with malignant disease is capable of destroying normal red blood cells. It also appears that while this fact is very interesting from a clinical and etiological standpoint, similar manifestations are possible in noncancerous patients. We ourselves have noted them in tuberculosis, syphilis, various forms of disease associated with anemia, in infective processes, and in one clinically normal individual. It would seem that in some cases where the nature of a pathological process is in doubt the hemolytic reaction might furnish information with respect to operative measures, inasmuch as we have noted it in the majority of malignant growths, while the majority of noncancerous but variously ill people and normal individuals fail to give us positive reaction. We have also shown that some cases, other than tuberculous, exhibit the phenomenon of "reverse hemolysis" and that others classed as "undetermined" hemolyze in both directions. As Crile has suggested, it would consequently seem to be quite necessary to estimate the hemolytic power of blood sera in cases where direct transfusion of blood is contemplated, else an already grave anemia may be rapidly changed to a fatal one. From the work of other investigators, and from our own, small as the series may be, it does not appear warranted to state that "reverse hemolysis" is characteristic in tuberculosis. We have shown that it does not always occur in proven tuberculosis, and that it occurs in other conditions. In conclusion, it should be emphasized that while the serum reactions for cancer and tuberculosis may furnish valuable and interesting information, they cannot be accepted as sole or deciding evidence. In confirmation of clinical findings they may be of importance, but as with other laboratory tests, of like nature, they cannot take the place of careful anamneses, careful examination of the patients from every viewpoint, and the adoption of clinical meas-

ures which have been proven feasible and dependable.

The writer's thanks are due to Drs. de Nancrede, Peterson, Lorce, Kollig, and Witter for opportunity of carrying on the work here outlined upon patients from their services at the University Hospital and their practices.

ATROPINE AS A HEMOSTATIC.

By WILLIAM F. WAUGH, A.M., M.D.,

CHICAGO, ILL.

PROFESSOR OF THERAPEUTICS, BENNETT MEDICAL COLLEGE.

Several years ago my attention was arrested by a recommendation of atropine as an effective hemostatic. I had just made a review of the literature on atropine, and its physiological action as stated by all the leading pharmacologists was such that one could but look on this suggestion as perilous to the lives of patients, since every element in the activity of this powerful alkaloid pointed to the conclusion that it must increase hemorrhage. For according to the best authorities atropine increased vascular tension, dilated the caliber of the arteries and capillaries, and increased the energy of the ventricular contractions. Luchsinger found that it caused an enormous rise of the pulse rate, which he attributed to paralysis of the intracardiac vagus ends, although he acknowledged that it antagonized the paralysis caused by chloroform, potash, oxalates, cholates, apomorphine, copper, zinc, antimony, or quinine.

Van Renterghem attributes the redness of the face and the upper parts of the body to the rapid pulse and the rise of blood-pressure. Zeller observed that a solution of atropine sulphate in a neutral solution of sodium chloride dilated the arteries, accelerating the circulation in the veins and capillaries, which were not dilated.

Albertini found that atropine added to the blood supplied an exsected organ caused the current to be briefly slowed and then much accelerated, which he attributed to relaxation of the circular fibers. By exciting the vasomotor center the vascular tension was raised in dogs, after large doses, that cutaneous vessels dilated while the cerebral vessels contracted, and the arterial tension was raised. The heart first slows when a toxic dose of atropine is taken, yet the slow pulse of muscarine is promptly quickened by atropine.

Here was certainly reason enough for us to rule out atropine from the list of probable hemostatics, and to look upon it as eminently calculated to increase bleeding, whether from the arteries, veins, or capillaries. But nothing is more liable to fallacy than *a priori* reasoning, especially when it is based on the presumption of the completeness of our knowledge of physiology and therapeutics. Besides, there was one notable contradiction between the experimental observations of the laboratory and the clinical evidence familiar to every practitioner—it was asserted that atropine caused a diminution of the quantity of blood in the brain, and this would necessarily tend to favor sleep; yet nothing in the effects of atropine is more certain than that it banishes slumber and generates a wild active delirium that by no stretch of imagination could be associated with cerebral anemia. Besides, the report I had received of the efficacy of atropine in checking hemorrhages was from a respectable source and the circumstances were too positive to suggest an error of observation or judgment. The matter appeared important enough to justify investigation.

The first step obviously was to establish the correctness of the premises. Single cases or even a series may be exceptional; the judicial faculty is rarely so developed as to render the testimony of one individual conclusive in scientific researches. Accordingly I advertised in journals going to 100,000 physicians for reports on atropine as a hemostatic. A large number of reports were received. Some of these were merely statements of the opinion that atropine could not be a hemostatic for reasons as detailed above. All the reports of cases in which it had been actually employed were favorable, testifying to the prompt and powerful influence of the alkaloid in controlling every form of hemorrhage to which human beings are liable, with the solitary exception of that due to the opening of a large artery. Several cases were reported of erosion occurring during typhoid intestinal ulceration or rapidly advancing pulmonary disease where atropine failed to control the hemorrhage. But it succeeded in active and passive, arterial and capillary, traumatic and hemophiliac forms of bleeding, and that with a promptness and completeness that left nothing to be desired.

By one of those annoying mistakes that occur in the best regulated offices, these reports were distributed in the general files of the journal I edited, before they had been copied and tabulated; and it was not possible to dig them out of a mass of correspondence from over 50,000 physicians. I therefore sent a circular note to every medical journal published in America asking for fresh reports. Knowing the tendency we all have to report successes, I specially requested reports of failures. Many of my colleagues responded to this request, but the reports did not differ materially from those previously sent to me—up to the present I have been unable to secure a solitary failure except when there is erosion of a large artery—and who could expect a drug to staunch such bleeding!

We therefore face one of those apparent contradictions, where unanimous and extensive clinical evidence shows results exactly contrary to those deduced from experimental investigation. I am not of those who insist on their own view, denying or ignoring the testimony of their adversaries. Honest, intelligent observations must agree if pushed to the point where the apparently divergent lines come together; and I believe that the present

furnishes a notable instance of this truth. It is not enough to assert that any agent does so and so, for we are learning to distinguish between primary and secondary effects, between those of large and of small doses, besides the modification due to conditions and environment. All accounts agreed that the hemostatic powers of atropine were manifested under the full effect of large doses, with the development of toxic symptoms, dry mouth, flushed face, and dilated pupils. Study of these clinical manifestations of atropine induces the conviction that its action is essentially active and not sedative. It is an excitant, not a paralyzer; and this extends through its entire field of action. If we accept the theory of a dual system of nerves governing the caliber of the blood-vessels, we may increase their caliber in one of two ways; by paralyzing the vasoconstrictors or by stimulating the vasodilators. If atropine did the first we should have a decided increase of hemorrhage from the relaxed, flabby capillaries. But how if atropine activated the hypothetical vasodilators? We would then have an actual increase of capillary attraction by which the blood would be drawn into the capillaries, necessarily lowering the tension in the arterial system. But a slight increase in the capillary blood-content would suffice to establish such a scarcity of blood elsewhere as promptly to check its loss, since the capacity of the capillary system is estimated at 700 times that of the arteries. Hemorrhage from arteries and veins would then be impossible on account of the increased attraction of the blood into the capillaries.

But how about capillary hemorrhages? Here we see the vast importance of the distinction between vasoconstrictor paralysis and vasodilator stimulation, for if by the latter the attraction of the capillaries for blood is increased by the forcible dilatation of their walls, if we cut through these vessels the blood would be retained within them and if the action is powerful enough we might even find air drawn into the open vessels.

This hypothesis involves the assumption that atropine in full toxic doses lessens arterial tension; and here let me quote one of the latest works on pharmacology. Sollmann says: "Quickening of the pulse is the principal effect of *moderate doses* of atropine on the circulation. The blood-pressure is scarcely altered; but there may be a slight rise. This stimulation is always slight and may be entirely absent; it is replaced by vasomotor depression rather early. *Large doses* depress the vasomotor center profoundly so that the pressure falls very low."

Doyon and Kareff have published several papers on the action of atropine on the coagulability of the blood. This is lessened by an injection of atropine into the portal vein, the effects, however, not being due to a direct action of the poison on the blood. If the blood is allowed to flow into a tube containing atropine solution coagulation is not perceptibly retarded, the effect being manifested only after the atropine solution has passed through the liver. Very small doses appear to hasten coagulation; large doses delay it, but only from ten to twelve minutes. Observers found that the injection of atropine, one centigram per kilogram, into an intestinal vein of a dog, induced narcosis with considerable lowering of arterial pressure. The pulse is very rapid, the impulses imperceptible, respiration is relaxed, and the amplitude of the respiratory movement is augmented. Little by little the heart pulsations are renewed and the effects pass off.

Among the numerous reports which I have received, I note especially some on placenta prævia, in which atropine was administered hypodermically until the mouth became dry, hemorrhage ceasing in all cases.

Others report the successful application of atropine in full dose in postpartum hemorrhage, menorrhagia, many cases of epistaxis, metrorrhagia, hemoptysis, quite a number of postpartum hemorrhage, hemophilia, intestinal hemorrhage, the hemorrhage following abortion, hematemesis, and one reports twenty-five cases of malarial hematuria in all of which atropine was successful. Among these there were some in which the use of quinine was invariably followed by hematuria, oozing of the gums, and hemorrhage from other parts.

Space forbids the quotation of these reports *in extenso,* and this is unnecessary since the matter is one which every physician in active practice can test for himself.

A STATISTICAL STUDY OF ALCOHOLISM AS A CAUSATIVE FACTOR IN INSANITY.*

By CLYDE R. McKINNISS, M.D.,

NORRISTOWN, PA.

FIRST ASSISTANT PHYSICIAN, STATE HOSPITAL FOR THE INSANE.

The statistics on alcoholism as a causative factor in insanity which we offer for your consideration are based on the admissions to the male department of the Norristown State Hospital for the Insane during the past two years—from April 1, 1907, to April 1, 1909. In that time 623 male patients were admitted, but as 103 of this number were returned from another institution where they had been temporarily detained, we do not include them in our study and thus have to consider 520 new admissions. Five of these were imbecile children from whom we could elicit no family history, but they were sent to the institution from Philadelphia by a society for the prevention of cruelty to children, which is alone significant. It might be said that our material is too limited to be of considerable value, but we have tried to increase its usefulness by obtaining some statistics from other sources. And the fact that these patients have been admitted from our own section of the state will add to their interest.

In studying our cases it soon becomes apparent that some presented the clinical pictures of psychoses which are classed as intoxication psychoses, while others would be of the manic-depressive, the præcox group, or other psychoses, tho' alcoholic excesses would be the apparent precipitating cause of the alienation. In another class of cases, alcoholism acted as an indirect cause. A few cases were admitted in which alcoholism in the parent at the time of conception appears to have influenced the mental development of the patient. Alcoholism in the parent after the child is born and as it grows to adult life undoubtedly has some influence upon its mental personality. The example of an alcoholic parent, with the often accompanying privations and laxity of morals, cannot but leave some impressions on the developing child, but as

*Read before the Psychiatric Society, Philadelphia, May 14, 1909.

we are unable to learn definitely the extent of these impressions, we have confined ourselves to the statement that the father or mother was alcoholic, when we found such to be the case.

Of the 520 cases admitted, alcoholism appeared to be an etiological factor in 240 cases, or 46 per cent., while of the 240 cases 71, or 13.6 per cent., were classed as alcoholic psychoses and divided as follows: chronic alcoholism 28, alcoholic hallucinosis 20, alcoholic hallucinatory dementia 11, alcoholic paranoia 10, dipsomania 1, Korssakow's psychosis 1; one of these, a physician, was also addicted to the use of morphine and hyoscine; eight had been admitted the second, and two the third, time to this or similar institutions.

In 37 cases a history of alcoholism in the parent was elicited, while in one the father was an epileptic, 36 were of Irish parentage, 20 of German, 7 English, 3 Italian, 1 French, 1 Austrian, 1 Swiss, 1 East Indian and 1 Negro. As to occupation: 46 were unskilled and 19 were skilled workmen, 4 were professional men and 2 had no occupation.

The remaining 169 cases, that is, 32.5 per cent. of those admitted, in whom we found a history of alcoholism, presented psychoses other than alcoholic and were classified as follows: In the manic-depressive group, 15 were mania, 15 depression, 1 hypomania, 1 stuporous mania. In the precox group, 12 were of the hebephrenic form, 9 of the katatonic form, and 21 of the paranoid form. There was one case of true paranoia, 11 epileptics, which is 34 per cent. of the total number of epileptics admitted, 28 paresis, 4 cerebral syphilis, 1 tabes, 26 senile dementia, 1 presenile, 14 imbeciles, which is 41 per cent. of the total number of imbeciles admitted; 7 melancholia, 1 traumatic, and 1 psychasthenia. Nineteen of these had previously been admitted to this or similar institutions, while in 82 cases a history of alcoholism in the parent was elicited. In one case the father and six brothers were alcoholics, and one brother was a suicide. In the 14 imbeciles, 9 were addicted to the use of alcoholics, while in 10 cases their fathers were alcoholic. In the 11 epileptics, 10 were addicted to the use of alcoholics and the fathers were alcoholic in 6 cases. Of the 28 paretics who gave an alcoholic history, 17 also gave a positive history of syphilis. In 3 cases of mania, alcoholic indulgence appeared to precipitate the attack, while in 8 cases of dementia præcox it acted in the same capacity.

Although in the remaining cases alcoholism cannot be said to be the direct cause, it was certainly a potent factor in causing the mental disease. Four of the cases had attempted suicide, 5 had made homocidal attacks which were not successful, 5 were murderers, 1 attempted criminal assault, and 5 were arrested for larceny.

We found whisky and beer to have been the principal beverages used, but we could not observe any relation between the beverages used and the psychosis produced. In some cases, and especially in the alcoholic hallucinosis, the psychosis developed while indulging regularly, though in others the mental symptoms developed only after withdrawal of the alcohol.

Doctor Mabon, of the Manhattan State Hospital at Ward's Island, kindly furnished us some statistics from that institution, with which we may compare our own. During the year ending Sept. 30, 1907, 1,516 patients were admitted to the Manhattan State Hospital and 201 cases or 13 per cent., were suffering from alcoholic insanity. For the year ending Sept. 30, 1908, 1,463 patients were admitted to the same institution, and over 13 per cent, were alcoholic psychoses, the largest proportion, however, being among the men, there being over 16 per cent., while among the women there was a little over 5 per cent. In a study which Dr. Mabon has made of 961 cases in which a dependable history could be obtained he found that either alone or in combination, alcohol was a precipitating cause in 37 per cent. Among the men the percentage reached 55 per cent., while in the women it was 22 per cent.

Kraepelin found that 30 per cent. of the male patients and 6 per cent. of the female admitted to the psychiatric clinic at Munich were suffering from psychoses due to alcohol. He also states that in 44.9 per cent. of the psychoses not directly due to alcohol this agent was an important factor in producing the mental disease. In epilepsy he found alcohol to be responsible for the commitment in 65 per cent. of males and 28.5 per cent. of female patients. In 42.9 per cent. of the imbeciles alcohol was the cause of their commitment.

Peterson places alcohol next to heredity as a single independent cause of insanity, and believes it to be the cause in 18 per cent. to 20 per cent. of the cases, being 3 or 4 times more frequent in males than females.

Doctor Cotton, in a paper on "Alcohol as an Etiological Factor in Mental Disease," states that of the patients admitted to the Danvers Insane Hospital, in Massachusetts, in 1906, alcoholic insanity was present in 25.6 per cent. of the male patients and in 15 per cent. when both male and female patients were considered, and that the percentage is gradually increasing.

Rosanoff in a recent article gives the following percentages for male patients whose psychoses were due to alcohol: In the State of New York 28.9 per cent., Massachusetts 30.6 per cent., in a group of three asylums in England 26.3 per cent., in a group of five asylums in Austria 24.9 per cent.

The percentages we have found at the Norristown Hospital are slightly lower than those of the other localities we have investigated, and this may be explained by the fact that some of our patients are admitted from rural districts, and in this city many are taken to the Insane Department of the Philadelphia Hospital.

SUMMARY.

I.—Our study includes 520 male patients, a majority of whom were admitted from Philadelphia and the larger towns in the Counties of Philadelphia, Delaware, Montgomery, Bucks, Lehigh, and Northampton.

II.—In 46 per cent. of these, alcohol either alone or in combination was an important etiological factor. In 13.5 per cent., they were classed as alcoholic psychoses.

III.—In 41 per cent. of the imbeciles and 34.5 per cent. of the epileptics, alcohol was responsible for their commitment.

Negro Physicians.—There are over 3,000 negro physicians in the United States. In a recent address before the Howard University Medical School, Booker T. Washington said there was a great opening for educated negroes in the medical profession in the South, and that there was room for at least 4,000 more.

MEDICAL RECORD.

JONNESCO'S METHOD OF SPINAL ANESTHESIA.

THE use of arachnoid injections of one of the cocaine substitutes as a means of inducing general anesthesia has not found great favor among surgeons in this country, although a few have employed them and some have advocated them strongly. The fact that this method could be used only when the lower part of the body was the seat of operation, injection into the upper part of the cord being rightly looked upon as dangerous, has had much to do with the disfavor with which the method was regarded. The feeling has been that, the danger of upper spinal injections being admitted, there was no guarantee that the influence of low injections might not extend upward to the bulbar region. Hence there was little disposition to flee from the familiar dangers of inhalation anesthesia to the unknown perils of spinal injection.

General spinal anesthesia has, however, had its enthusiastic advocates in France and elsewhere on the Continent, and at the International Congress of Surgery in Brussels in September, 1908, Jonnesco of Bucharest read a paper advocating this method for operations in the upper as well as in the lower part of the body, claiming that the addition of strychnine to the anesthetic deprived the procedure of all danger even when injection was made into the arachnoid of the upper dorsal spine. The paper was not particularly well received, and Bier of Berlin, Rehn of Frankfort, and others in Germany have warned their colleagues against a resort to what they consider a dangerous measure. In answer to their condemnation, Jonnesco went to London and is coming to this country to show by practical demonstration in the operating room that his method is not only safe but possesses numerous advantages over inhalation anesthesia.

In the *British Medical Journal* of November 13, Jonnesco writes that since October, 1908, he has used spinal anesthesia in all his operations, hospital and private, never once having recourse to anesthesia by inhalation, and his hospital colleagues have also employed the method with complete success. The two essential points of novelty are: (1) That the puncture is made either in the dorsolumbar region, for operations on the abdomen or lower extremities, or between the first and second dorsal vertebræ, for operations on the upper portion of the body or the head; and (2) that strychnine is added to the anesthetic, this addition preventing, it is claimed, the occurrence of bulbar symptoms when the higher injection is made. Among the advantages which the writer claims for general spinal anesthesia are that it can be given by the surgeon himself, thus doing away with the need of a special anesthetist and so reducing the number of assistants; that it can be used in any case with absolute safety, there being no contraindication to its employment; that it greatly simplifies operations on the face or throat by doing away with the troublesome mask; that it usually is attended by immobility of the limbs by reason of the paresis resulting from the anesthesia of the spine; and finally that there is immobility of the abdominal viscera, including the intestines, the advantage of which in cases of laparotomy can hardly be overestimated.

Concerning the safety of the method Jonnesco speaks with the most absolute confidence, with a disquieting confidence indeed, for it is not founded on a sufficiently long or wide experience. He has used it in 412 cases, 295 dorsolumbar injections, and 117 upper dorsal injections, and his colleagues, Jiano and Nasta, have used it in 211 cases, 172 dorsolumbar and 39 dorsosuperior injections—a total of 623 operations in the course of a year, without a death and without any serious complications. In addition, Jonnesco had 603 cases of lumbar anesthesia before he began to use strychnine, all without any untoward complication. That is indeed a strong showing and explains, even if it does not entirely justify, the author's confidence. The cable reports that he has overcome the conservatism of the London surgeons and has demonstrated the method in some of the hospitals in that city, and it adds that he will soon come to America to urge the practice of general spinal anesthesia upon his professional brethren here.

THE STATUS OF THE NEW TESTS FOR TUBERCULOSIS.

ENOUGH time has elapsed since the introduction of the cutaneous and the conjunctival tests for tuberculosis to admit of judging, more or less finally, their value in the practical problems of diagnosis. The busy practitioner, however, will find it very difficult to form a personal judgment in the matter, because of the necessarily limited material and the infrequent autopsies he sees, while the current medical literature has been full rather of enthusiastic or polemical articles than of careful consideration of the reactions in question. It is to be welcomed, therefore, that Bandelier and Roepke have thought it fit to give a great deal of space to these questions in the third edition of their book on the specific diagnosis of tuberculosis.*

They first consider von Pirquet's cutaneous test which, if positive, results in an inflammatory reaction at the site of inoculation with tuberculin after the lapse of from three to 48 hours. The specific character of the reaction cannot be doubted:

*Bandelier and Roepke: "Lehrbuch der specifischen Diagnostik und Therapie der Tuberculose," 1909.

v. Pirquet's autopsy material numbering several hundred cases, showed anatomical lesions of the disease in the great majority of patients who gave a positive reaction in life. Moreover, the inflammatory lesion at the site of the inoculation shows the histological structure of a tubercle, characterized by the presence of Langhans' giant cells, surrounded by numerous epithelioid and round cells. Beyond an occasional slight general disturbance or an unusually marked local reaction, the test as prescribed by von Pirquet, with the usual care in technique, has proved completely harmless. Negative results have been obtained in the presence of tuberculosis in the last stages of the disease, in many cases of miliary tuberculosis and of tuberculous meningitis, after prolonged treatment with tuberculin, and frequently in cases of coexistent measles. It is evident that in many of these instances the failure to obtain a reaction in a manifestly tuberculous patient may have some prognostic as well as a diagnostic significance. A late reaction, occurring after more than twenty-four hours, has usually been seen in clinically negative cases and only exceptionally in manifestly tuberculous patients. Of the latter, 96 to 98 per cent. of the immense material observed have given a positive reaction.

The real value of the test, however, lies in the diagnosis of tuberculosis in childhood. The percentage of positive reactions increases steadily and proportionately with the increase in age, and these results have proved to be quite parallel with the pathological findings at autopsies. Newborn children give a negative reaction without exception. A positive reaction in an infant below one year of age almost infallibly shows the presence of tuberculosis; a negative result means absence of the disease, if cachectic patients suffering from a manifest infection be excluded. In other children the reaction is the more valuable the nearer they are to infancy; a negative reaction speaks almost infallibly for absence of tuberculosis. A positive result in the great majority of cases means the presence of an active tuberculous process. Von Pirquet's test, therefore, is indicated in practice among children, its general applicability, easy technique, harmlessness, and specific character making it perhaps the most valuable single measure of diagnosis.

Bandelier and Roepke have hardly any words of commendation for the conjunctival test. It is evident, of course, that this test is dangerous. Moreover, it is contraindicated in the presence of most external affections of the eye, in which the specific reaction cannot be judged. Finally, if positive, it speaks only for the presence of a frankly tuberculous process which can be diagnosed by other methods. If negative, it is of no value, for it is not nearly as sensitive as the cutaneous test. Thus this test, the authors contend, so indiscriminately used at first, finds hardly any excuse for being included among diagnostic measures in tuberculosis. The damage that may be caused by it should restrict its application to the few cases in which some special reasons might call for it.

On the other hand, Bandelier and Roepke hold, the cutaneous test must be looked upon as a most valuable addition to the means of diagnosing tuberculosis. Its special value in the tuberculosis of children should lead to its wide employment among these patients, so that curative and prophylactic measures may be instituted at an earlier date than the results of physical examination or the general symptoms have justified in the past.

Toxic Arthritis of the Hip

The diagnosis of disease of the hip joint is not, as a rule, considered to be a matter of great difficulty. The proper appreciation of the significance of the referred pains, limp, tenderness, spasm, restriction of motion, and other signs described in every text book of surgery, leads the careful examiner almost at once to a localization of the trouble to the hip joint, and when once this is determined the chances are considered so overwhelmingly in favor of the process being tuberculous, that the diagnosis of tuberculous arthritis is promptly made; for, ruling out neuroses, syphilis, and rheumatism, which can usually be done from lack of signs elsewhere, there is but little else which comes into consideration. In the August number of the *American Journal of Orthopedic Surgery*, however, Hoke calls attention to a new variety of arthritis of the hip, called by him "toxic arthritis," which so closely resembles tuberculous disease of the joint that it may be expected in the future to make the diagnosis of trouble in this region more difficult than it has been in the past. The cases as reported by Hoke occurred in children and began in the manner typical of tuberculosis of the hip, with pain, limp, spasm, deformity, and fever. Clinically the affection could not be told from the early stage of tuberculous arthritis. In most of the cases, however, there was a history of improper dieting or indigestion, and there were found in the urine excessive amounts of indican, phenol, or indol acetic acid, suggesting intestinal putrefaction. The patients were put to bed, given a clearing out with castor oil, and placed on a lactofarinaceous diet, and the bowels were irrigated twice daily. In the acute cases this treatment caused a complete disappearance of all symptoms in the course of a few days, and proper dieting produced a permanent cure. In the chronic cases the head of the bone softened, bone atrophy occurred, and operation became necessary. In such cases the clinical diagnosis was especially difficult, as the destruction of the bone and consequent shortening of the limb added to the confusion. A characteristic of these cases of "toxic arthritis" was that they did not suppurate; the joints often became distended with fluid, but of a straw color and sterile. The cases, as a rule, gave negative reaction to tuberculin, though in a few cases the association of "toxic arthritis" of the hip, with tuberculous lesions elsewhere, rendered the diagnosis especially obscure. The recognition of these cases of toxic arthritis, if the findings of Hoke are confirmed, is an observation of far-reaching import. In his clinic at Atlanta, such cases made up a majority of the affections of the hip seen. If the disease is allowed to progress it leads to deformities, which, except for suppuration and the tendency to generalization, are quite as serious as those seen in true tuberculous osteoarthritis; whereas, if recognized early a simple dietetic and enteric treatment causes complete and prompt recovery. The possibility of such a condition should be borne in mind in

the consideration of every child suspected of hip joint disease. If it actually exists, the appreciation and recognition of it may lead to the prevention of years of suffering.

Can Deaf-Mutes Swim?

In the *Journal of Laryngology* for November, 1909, Daniel Mackenzie refers to a statement made in a discussion at the French Congress of Otology, by Moure and Cauzard, who reported on the recent improvement in our methods of diagnosing labyrinthine disease. They quote an American observer that it is "almost impossible for deaf-mutes to swim." Mackenzie, however, says that what was referred to was the difficulty which deaf-mutes experience when they try to swim under water. If the recent experiments of Thomas be accepted this inability would seem to be a result of the absence or paralysis of the vestibular apparatus. Having cut the vestibular nerves of dogs, Thomas found that the animals could not maintain their balance under water, but if these nerves were left untouched and the cerebellum was destroyed, they could manage themselves very well. Mackenzie quotes from a letter received from the head master of one of the English institutions for the instruction of deaf and dumb children, who says that they teach all their pupils there to swim unless there is some special medical contraindication. They seem to learn the art quicker than normal children and become proficient swimmers. They cannot, of course, direct themselves by sound though they swim perfectly well with eyes closed. This same writer adds that the discrepancy between the older reports and the more recent statements is more apparent than real. In many deaf-mutes—the majority—the vestibular sense is active and these persons have no difficulty in swimming. If the vestibular end organs are totally inert the ability to support oneself under or on water would probably depend on the character and duration of the destructive lesion and upon the presence or absence of an education of the compensatory methods of maintaining the equilibrium. Certain deaf-mutes find it difficult to walk in the dark or with eyes bandaged and these we should expect to be the individuals in whom the vestibular end-organs have been but recently destroyed or who have neglected to train their sense of touch and pressure to replace the defective stimuli from the semicircular canals.

A Neurological Institute.

In casting up the evils of Christian Science and its imitators, one should not forget that some good has come from them in the way of an awakening of the medical profession to the necessity of a more general study and knowledge of so-called functional nervous diseases. It must be confessed that the general practitioner has hitherto not given the attention and the thought to these distressing conditions that their seriousness demanded, and some such outside demonstration of their prevalence and of their amenability to treatment was perhaps necessary to open his eyes to the fact of his neglect. Even neurologists have been remiss in this matter, for with all the institutions, both hospital and dispensaries, for the treatment of the indigent sick in the larger cities of this country, there is no place to which the subjects of "functional" nervous diseases or mental disorders not amounting to actual insanity can go for care and treatment. The general hospitals will not receive them, and if they did the sufferer would get little relief even if his condition were not aggravated by a stay in such a place. To supply this need an institution has now been established, as noted in our news columns, for the study and treatment of nervous and mental diseases. Such an institution will doubtless be of great service to the sufferers from those hitherto more or less neglected affections, not only directly in relieving them of their troubles, but also indirectly as an educational center for the spread of greater knowledge regarding these maladies and their cure.

News of the Week.

Fifth Course of Harvey Society Lectures.—The Harvey Society lectures for the coming season will be given on Saturday evenings, at 8:30, in the Academy of Medicine, 17 West Forty-third street, New York, as follows: *December* 4, Prof. Otto Cohnheim, University of Heidelberg, "The Influence of Sensory Impressions on Scientific Deductions." *December* 11, Prof. T. G. Brodie, University of Toronto, "Renal Activity." *December* 18, Prof. Carl G. Huber, University of Michigan, "Renal Structure." *January* 15, Prof. Ludwig Hektoen, University of Chicago, "On Certain Phases of the Formation of Antibodies." *February* 19, Dr. Eugene L. Opie, The Rockefeller Institute, "Inflammation." *March* 5, Prof. Adolf Meyer, Johns Hopkins University, "The Present Status of Aphasia and its Relation to Psychopathology." *March* 19, Prof. A. Magnus-Levy, University of Berlin, "Pathology and Therapy in Diseases of Metabolism." *April*, Prof. Jules Bordet of the Pasteur Institute of Brussels is expected to deliver a lecture before the Society in April. The exact date and title will be announced later.

A Department of Public Health.—It is stated by the Washington correspondent of *The New York Times* that a report on a plan for a Federal Department of Public Health has been submitted to President Taft by Dr. Walter Wyman, Surgeon-General of the Public Health and Marine-Hospital Service, at Mr. Taft's own request. Such a department or bureau was recommended in the platform of both the Republican and Democratic Parties, but in spite of that, it is not thought likely that any action will be taken at the present session of Congress.

Mortality in American Cities.—The official figures on the general death rates of the seven cities having more than 500,000 population are as follows: Chicago, 14.03; St. Louis, 14.52; Pittsburg, 16.49; New York, 16.83; Philadelphia, 17.39; Baltimore, 18.32; Boston, 19.08. The typhoid fever rate was highest in Pittsburg, 46, and lowest in New York, 12. Chicago had the second lowest typhoid rate—fifteen per 100,000 of population. Tuberculosis was lowest in Pittsburg, 139; second lowest in Chicago, 181; and highest in Baltimore, 250 per 100,000 of population. Pittsburg had the largest proportion of pneumonia deaths—229 in each 100,000 of population; New York was second highest with 212, Boston was third with 188, and Chicago was fourth with 162. St. Louis had the lowest pneumonia rate, 114. The four chief acute contagious diseases that menace child life—diphtheria, scarlet fever, measles, and whooping cough—were most fatal in Boston—101.4 per 100,000 of population—and second highest in New York—94.8. Self-destruction was most

commonly practised in St. Louis, where, according to the tabulations of the United States census office, 32 out of each 100,000 of its citizens ended their lives by suicide. In New York and Chicago the proportion was 23; in Boston and Pittsburg, 21; in Philadelphia, 18, and in Baltimore, 17.

The Good Effects of Water Filtration.—Since the introduction of water filtration there has been a gradual reduction in the number of cases and of deaths from typhoid fever in the city of Philadelphia. For the week ended November 13 there were twenty-five cases reported, with but one death. Prior to the year 1904, when the first division of the water filtration system was put in operation, the number of cases of typhoid fever was upward of 400 a week and the number of deaths upward of 20. In that year there were 6,587 cases of the disease reported, an average of 127 a week, with 744 deaths, or an average of 14 a week, as compared with 8,701 deaths, an average of 167 a week, with 957 deaths, or an average of 18 a week, in the preceding year.

Pensions in State Hospitals.—The conference of medical superintendents and managers of State hospitals, with members of the State Lunacy Commission, decided recently to favor legislation at the coming session to provide for an increase of about 20 per cent. in the salaries of attendants and nurses in the State hospital service. It is contended that the State's force of employees is constantly being disorganized because outside institutions pay higher wages than the State and as soon as the employees become valuable they leave the hospitals for the more lucrative positions in private institutions. Dr. Mabon, medical superintendent of the Manhattan State Hospital, presented a paper which recommended a system of annuities to be paid not only to the employees but also to members of the medical staffs of State hospitals if they serve for twenty-five years or longer. This proposition was indorsed by the conference.

Pellagra in Cleveland.—The first case of pellagra to be diagnosed in Cleveland, O., was reported to the Federal authorities recently. The case was found in the Cleveland City Hospital.

Antituberculosis Campaign in Ontario County, N. Y.—An active campaign for the eradication of tuberculosis in Ontario County, N. Y., has been begun. An enthusiastic meeting of the county organization was held recently and Robert H. Pierce of Albany was appointed special field agent. This means that the County of Ontario will have the benefit of the services of a paid secretary, who will devote his entire time to educating the public in the fundamental facts of the disease and encouraging action towards its suppression. He will be furnished with an exhibit by the State Charities Aid Association of New York, which he will take from town to town. Every home in the county will have literature on tuberculosis. Committees are already formed in Geneva, Canandaigua, Allan's Hill, Clinton Springs, East Bloomfield, Naples, Seneca Castle, and Stanley. Committees will be formed in the other towns and villages in the county. It is expected that every community will have such a committee and in this way the whole county will be aroused. The office and headquarters will probably be in Geneva, where active work has already been done through the efforts largely of Mr. H. B. Graves, president of the committee, and Dr. C. C. Lytle, secretary.

A Neurological Hospital and Dispensary will be opened on November 29, at 149-151 East Sixty-seventh street. Under the name of the Neurological Institute, it has been incorporated in accordance with the laws of the State of New York as a public hospital for the study and treatment of nervous and mental and allied diseases. The hospital consists of two wards, one for males and one for females, into which suitable cases will be received free of charge, of private wards in which a charge will be made for care and treatment, and of private rooms. The Dispensary will be open daily except Sundays and holidays, from two to four for charity cases only. During these hours, one of the medical board and his assistants will be in attendance. Physicians are invited to send patients suffering from nervous, mental, and allied diseases to the dispensary for diagnosis and for treatment, or for admission to the wards. Patients bringing letters from their physicians requesting diagnosis or suggestions in regard to treatment will be referred to their physicians. In addition to the medical board, the medical staff will consist of a surgeon, an orthopedic surgeon, an ophthalmologist, a psychologist, a resident physician, and a laboratory director. Courses of instruction will be announced later. The medical board is composed of Drs. Joseph Collins, Joseph Fraenkel, and Pearce Bailey.

Yellow Fever in Yucatan.—Yellow fever has again made its appearance in Yucatan. Four cases are reported at Merida and one in the interior.

Refraction by Practitioners.—The committee appointed by the Ophthalmic Section of the American Medical Association to "promote a working knowledge of simple refraction among family physicians" has issued a letter in which it is urged that the State Boards of Registration require it for license and medical colleges teach it in course.

Ungallant Medical Students.—A cable despatch to *The Sun* states that the annual examination list of the medical students in the Paris hospitals is headed for the first time on record by a woman, Mlle. Romme. Her male competitors greeted the result of the examination with cries of "Conspuez le jury!" The disturbance lasted for a quarter of an hour.

Charitable Bequests.—By the will of the late Emanuel Ernestine of Pompton Lakes, N. J., the Mount Sinai Hospital in New York will receive $10,000, and the Montefiore Home $5,000.

House Staff Resigns.—Owing to a disagreement between the superintendent of the Washington Heights Hospital in New York as to remuneration for the signing of insurance certificates, one of the three internes was dismissed, and the two other internes promptly resigned, their resignation taking effect as soon as their positions were filled.

Licenses Revoked.—For the first time under the new laws of Arkansas, the State Medical Board has revoked the licenses of two physicians. The cause was "fake" advertising.

Fourth International Sanitary Convention.—The Secretary of the Treasury has selected the following persons as representatives at the Fourth International Sanitary Convention to be held at San José, Costa Rica, from December 25, 1909, to January 2, 1910. Surgeon-General Wyman, P. A. Surgeon J. W. Amesz, P. H. and M. H. S.; Dr. H. M. Bracken, Secretary of the State Board of Health of Minnesota; Dr. A. H. Doty, Quarantine Officer

of the Port of New York; Dr. Rhett Goods, member International Sanitary Bureau of Washington.

The Association of French Physicians of North America.—The fifth congress of this association will be held at Sherbrooke, P. Q., during the second week of August, 1910. This date is selected to enable the members to attend the meeting of the Canadian Medical Association during the last few days of August. The president of the association is Dr. P. Pelletier of Sherbrooke, the secretary is Dr. Frederick A. Gadbois of Sherbrooke, and the treasurer is Dr. J. Omar Ledoux of Sherbrooke.

The Pendleton (Ore.) City and County Society was organized November 4, and the following were elected officers: *President,* Dr. A. J. Best; *Vice-President,* Dr. D. J. McFaul; *Secretary-Treasurer,* Dr. I. U. Temple.

The Rockingham County (N. H.) Medical Society held its fifth annual meeting at Portsmouth, November 11, 1909. The election of officers resulted as follows: *President,* Dr. E. A. Landman of Plaistow; *Vice-President,* Dr. Thomas W. Luce of Portsmouth; *Secretary,* Dr. Walter Tuttle of Exeter; *Treasurer,* Dr. Alice Chesley of Exeter.

The Fond du Lac County Medical Society at its seventh annual meeting, held November 10, 1909, elected the following officers: *President,* Dr. Schoofs of Johnsburg; *Vice-President,* Dr. G. T. McDougall; *Secretary and Treasurer,* Dr. Flora Read.

The Jewish Hospital of Brooklyn.—At the annual meeting of this institution, held last Sunday, it was announced that an isolation building, a septic pavilion, and a laboratory would be added. The hospital has also undertaken the construction of a nurses' home and training school.

Obituary Notes.—Dr. William Adie Bell of Yonkers, N. Y., died November 15, 1909, at the bedside of a patient. He was 58 years of age, a graduate of the College of Physicians and Surgeons in New York, in 1886, and a member of the Westchester County Medical Society and the New York State Medical Association.

Dr. Charles E. Hall of Greenville, N. H., died suddenly November 7, 1909, aged 62 years. He was a graduate of Dartmouth College and of the New York University Medical College, in 1873. Dr. Hall, besides practising his profession, was proprietor of a drug store, and a politician, having been a member of both houses of the State Legislature.

Dr. Franklin B. Ives of Long Beach, Cal., died November 2, 1909, aged 86 years. He was a graduate of the Rush Medical College, in 1850, and practised medicine in Chicago for forty years. About twenty years ago Dr. Ives retired from the practice of medicine, and was ordained a minister in the Baptist Church. He had lived in Long Beach for the past fourteen years.

Dr. James W. Stewart of Rumford, Me., died November 10, 1909, aged 65 years. He was a graduate of the Medical School of Maine, in 1873, and a member of the Oxford County Medical Society and the Maine Medical Association.

Dr. David H. Beckwith of Cleveland, O., died at his home, recently, aged 85 years. A graduate of the Eclectic Medical Institute of Cincinnati, in 1851, Dr. Beckwith soon became associated with the Cleveland Homeopathic Medical College, in which institution he held a professorship for over fifty years.

Correspondence.

THE AURICULO-VENTRICULAR BUNDLE AND STANLEY KENT.

To the Editor of the Medical Record:

Sir:—In a recent issue of the Medical Record[1] Dr. S. J Meltzer calls attention to what he believes to be an injustice to the work of Stanley Kent in regard to credit for the detection of the auriculo-ventricular bundle and for the determination of its function. Dr. Meltzer says in this connection: " . . . Two publications appeared nearly simultaneously by Kent and His, describing *a bundle of muscle fibers** entering from the right auricle into the septum and branching out into both ventricles." "Everybody knows His and his bundle, but very few know of the share which Kent had in the detection of that bundle. Kent's publication *on the bundle** appeared at least simultaneously with that of His. Furthermore, Kent was apparently more correct than His in the description of the structure of these fibers, and in his important reference to their embryonic character. Now, in studying original articles, I discovered that Kent also performed the experiments of Erlanger apparently by the *same method and with the same success.* They are mentioned in Kent's article which was published fifteen years ago."

It is implied or stated in as many words in the passages quoted above (*a*) that Kent described the auriculo-ventricular bundle, (*b*) that Kent determined the function of that structure, (*c*) that Kent's experiments and those of the writer, not to mention those of other experimenters who have been engaged in the elucidation of the same problem, are identical, and (*d*) that Kent's work has not received the notice it deserves. We are satisfied, as must any one be who, like the writer, has experienced the pleasure and stimulus of knowing him, that Dr. Meltzer was impelled to the publication of these views by that inestimable trait of character that insists upon the placing of credit where there is even the slightest reason for believing that credit is due. It is therefore to be regretted that in his effort to do justice to the work of Kent, Dr. Meltzer has failed to recognize its true significance in relation to the contributions of subsequent investigators; it is to be regretted that each of the implications or statements mentioned above is, in our opinion, incorrect. And lest these errors be perpetuated in the literature, I have reluctantly decided to call the attention of the readers of this journal to what I believe to be Kent's real relation to the development of the subject in hand.

We may begin this discussion with an analysis of Kent's contribution. The problem to be solved is clearly stated in his introductory remarks.[2] After calling attention to the fact that in cold-blooded animals "the muscular tissue constituting the various chambers of the heart . . . is perfectly continuous from sinus venosus through the auricles into the ventricle," and that "the explanation of the passage of a wave of contraction over the various chambers is upon exactly the same footing as the explanation of the passage of a wave of contraction along any other continuous stretch of muscular tissue, he proceeds to say that in mammals "a distinct break has always been described as existing between the muscle fibers of auricle and ventricle. The existence of this break," he continues, "has rendered inadmissible any explanation which depends upon muscular conduction . . ." For this reason he undertakes a study of the auriculoventricular ring he undertakes a animals for the presence in it of muscle fibers.

It would require too much space to give here his results in full. It is therefore fortunate that Kent himself has supplied us with an abstract of his work.[3] This was read eight months after the full report of his experiments had been placed in the hands of the editor: "In the hearts of newly-born rats a complete muscular connection exists between auricle and ventricle in the following situations: (*a*) Between the outer wall of the right auricle and right ventricle; (*b*) between septum of auricles and septum of ventricles; (*c*) between outer wall of left auricle and left ventricle. In the adult rat a similar connection exists, though the details are modified in consequence of the development of a mass of connective tissue for the support of the auriculo-ventricular valves.

"In the rabbit the development of fibrous tissue at the base of the valves is still more pronounced, though the muscular fibers appear to be still continuous between the two cavities.

"Between the auricle and ventricle and lying in the connective tissue ring are modified muscle cells, usually

* Italics mine.

spindle shaped, nucleated, granular, becoming extremely narrow in parts and then swelling out again, transversely striated, branched, and usually connected into a network. These cells are somewhat rudimentary in the case of the rat and are very well developed in the monkey. In the latter animal they exist as a complete network, penetrating the fibrous connective tissue of the groove and extending through from auricle to ventricle. Upon approaching the groove the normal cardiac fibers split up into similar fibers and become connected with the network of cells lying in the fibrous tissue."

There cannot be recognized in this full transcription, or in Kent's full report, any structure that answers to the description of the auriculo-ventricular bundle. Indeed, Kent does not even hint at the existence in any heart of but a single sharply differentiated bundle of muscle fibers located in the septum and nowhere else. That he may have seen the auriculo-ventricular bundle among the numerous other connections which he believed were muscular cannot be denied; neither can it be affirmed that he did see it and describe it.

Kent published in connection with his article six beautiful plate figures. A careful examination of these plates fails to reveal the auriculo-ventricular bundle. Nor is it stated in the accompanying descriptions that any of the figures picture the septum of the heart; whereas it is definitely stated that two of the sections, showing what Kent believed were broad muscular connections, are from "the junction of the left auricle and the left ventricle." These could not possibly have contained the auriculo-ventricular bundle.

At this place reference should be made to the claim of some Italian authors, *i.e.* Luciani,[4] that the auriculo-ventricular bundle was discovered by Paladino in 1870.* Unfortunately I have been unable to secure a copy of Paladino's original article. Retzer,[5] however, says that he has failed to find any statement in it that could be construed as meaning that muscle fibers cross through the auriculo-ventricular junction.

Kent's histological work has been referred to by all subsequent workers in the same field. The paper by His, Jr.,[6] describing the auriculo-ventricular bundle appeared at about the same time as Kent's. In a subsequent paper His[7] briefly reviews his own work and at the same time brings Kent's into relation with it. Be it here recalled that in the interim His had not repeated his own work nor that of Kent. He says: "In man, indeed in mammals in general, a layer of connective tissue grows in between the muscle walls of the ventricles and auricles and separates these parts almost completely. Nevertheless, muscle fibers have been found in this layer (Stanley Kent), and I myself have demonstrated a bundle, present in mammals as well as in man, which courses from the posterior wall of the right auricle to the ventricular septum." Retzer,[5] Braeunig,[8] Humblet,[9] Tawara,[10] and others all confirm His to the effect that crossing the auriculo-ventricular junction there is to be found in the heart of warm-blooded animals but a single discrete bundle of muscle lying in the septum of the heart. There is still some difference of opinion as to the exact mode of origin and termination of this bundle and as to the histological characteristics of the cells of which it is composed, but all are agreed that it lies in the septum of the heart. None have succeeded in finding muscular connections in any other part of the heart.

Retzer[5] attempts to account for Kent's finding muscle fibers in other places by calling attention to the fact that the latter "used picrocarmine for the differentiation of musculature and connective tissue. This method," he says, "is, however, very unreliable, as one can easily determine for himself."

Braeunig,[8] referring to Kent's work, says in one place that he could not discover in any of the hearts studied a muscular connection similar to that described by Kent as existing in the monkey's heart. And whereas he thinks that Kent's findings in the undeveloped heart of the new born rat may be of great significance, they are wholly without significance in so far as concerns the fully developed mammalian heart.

Finally, Tawara[10] says in this connection: "Kent's description of the finer histological details agrees very well in some points with my observations. But I have found this peculiar connecting bundle only on the boundary between the septum atriorum and ventriculorum, never in the auriculo-ventricular groove. . . . The actual discovery of the auriculo-ventricular bundle in man and mammals we owe to His."

It is evident, therefore, that Kent should not be credited with having discovered and described the auriculo-ventricular bundle. The credit that is Kent's is that he was one of the first investigators to attempt to demonstrate by means of histological methods a muscular connection between the mammalian auricles and ventricles. Practically every paper purporting to give a more or less complete review of this subject refers to Kent's work in connection with it; we mention, for example, the reviews by Gaskell,[11] Langendorff,[12] Hoffmann,[13] His,[7] Hering,[14] Humblet,[9] Retzer,[5] Braeunig,[8] Tawara,[10] Erlanger,[15] and others.

Since Kent did not know the auriculo-ventricular bundle and since he believed that muscular connections existed in practically every part of the auriculo-ventricular junction, there can be no valid reason for maintaining that Kent devised experiments for the purpose of blocking the passage of the excitation wave through that particular structure. Kent's own statements permit us to go even further than this: he made no effort to block the passage of the excitation wave through those structures which he believed to be muscular to the exclusion of other parts of the auriculo-ventricular junction.

Kent's account of this phase of his work is extremely brief, being contained in practically four lines. It is preceded by the following paragraph: "It has been shown by Gaskell that in the frog a similar (partial and complete) block may be produced by a gradually increasing compression of the tissues at the auriculo-ventricular groove, and by a specially constructed clamp he has been able to so apply the pressure to the excitable structures as to obtain results almost identical with those described above as the result of section in the tortoise heart." Then follows the account of his experiments which is here *transcribed in full:* "In the case of the mammalian heart almost precisely similar results may be obtained by the use of a suitably constructed clamp, and using such an instrument I have been able to verify for the mammalian heart almost all of the effects described by Gaskell as obtained in the frog." Finally, in his conclusions, Kent refers to this phase of his work as "the effects of compression on the auriculo-ventricular *groove.*"*

In view of the fact that Kent does not furnish proof that his clamp was applied accurately to the auriculo-ventricular groove, the statement may be interesting, that results similar to those obtained by Kent may follow functional separation of any more rhythmical part of the heart from a part less rhythmical. It is therefore possible that his clamp might not have included in its grasp even the structures he describes in the anatomical section of his paper, not to mention the auriculo-ventricular bundle.

With the experiments demonstrating that the auriculo-ventricular bundle constitutes the sole functional connection between the auricles and ventricles, the readers of this journal are probably familiar. They can be divided into two groups: (1) Those in which practically nothing but the auriculo-ventricular bundle was cut in the perfused heart (His[16] [?], Humblet,[9] Hering[14]); and (2) those in which practically nothing but the auriculo-ventricular bundle was gradually compressed in a special clamp, the heart preserving its normal relations to the organism (Erlanger,[17] v. Tabora[18]). These two types of experiments bear the same relation to each other as do the experiments of Wooldridge and Tigerstedt (mass ligation of the entire auriculo-ventricular junction), upon the one hand, to those of Kent on the other. And this constitutes Kent's only contribution to this phase of the subject.

If we admit that Kent's histological findings are correct, then, in view of this recent work, we find ourselves in an interesting dilemma. Experiment has conclusively proved that the cardiac excitation wave is blocked when of all of the auriculo-ventricular junction practically nothing but the auriculo-ventricular bundle is injured. Now Kent describes muscular connections in remote parts of the auriculo-ventricular junction. It follows that the excitation wave is not conducted through muscular tissue, and the neurogenic theory is proved. It is fortunate, therefore, for the defenders of the myogenic camp that recent work does not substantiate Kent in this regard.

It will not be superfluous to state in conclusion that the writer became acquainted with Kent's experiments while he was engaged in his investigation into the function of the auriculo-ventricular bundle, but not until after his plans had been fully developed. Had he, however, known it sooner it would have been considerably less of help to him in devising his experiments than was Gaskell's work, with which every modern student of physiology is perfectly familiar. Kent's experiments, so far as can be determined from his own account, were a perfect repetition, upon warm-blooded animals, of Gaskell's. Gaskell, however, de-

* Luciani merely says that Paladino found muscle fibers crossing the auriculo-ventricular junction.

* Italics mine.

scribes methods and pictures results; Kent does neither. Had the writer been engaged in Kent's particular problem it would have been necessary for him to work out for himself every technical detail connected therewith. Our problems, it has been seen, were, however, quite different. There may be some who will maintain that I was remiss in not calling attention to this difference. My only defense is that others who have concerned themselves with the physiology of the auriculo-ventricular bundle (His,[16] Humblet,[9] Hering,[14] v. Tabora[15]) are equally culpable in that they too fail to see the relation between their problem and that of Kent.

JOSEPH ERLANGER, M.D.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Regarding the objections raised by Dr. Erlanger to my giving credit to Stanley Kent for his share in establishing the existence and significance of the atrioventricular conducting fibers,[1] I am ready to stand corrected and willing to be more explicit on the following points: 1. Kent described muscle fibers connecting the auricles with the ventricles, but did not mention specifically the "bundle"; 2. Kent has not determined the function of the "bundle" but that of the muscle fibers which connect the auricles with the ventricles; 3. the experiments of Kent were not exactly identical with those of Dr. Erlanger, who compressed the nearly isolated bundle, whereas Kent compressed all the tissues of the septum connecting the auricles with the ventricles.

After these admissions I must confess to a feeling of real regret for the attitude which Dr. Erlanger in his letter assumes toward Kent and his work. In the first place, assuming even that all which Dr. Erlanger has to say of this work is unassailable, his position seems to me to be nevertheless unjustifiable. Kent's work and merit ought to be judged particularly with reference to the situation and time when the work was done. Gaskell and Engelmann claimed that the cardiac impulses are exclusively originated in and transmitted through muscle fibers. The experiments supporting this claim were made on amphibia in which animals' muscle fibers were present which connect auricles and ventricles. The delay in the transmission of the wave of contraction from auricle to ventricle Gaskell explained by the assumption that the transmitting muscle fibers are of embryonic nature. By means of a clamp Gaskell has further shown that by a gradual compression of the connecting fibers in the amphibian hearts the ventricular rhythm will gradually pass through all the phases of an incomplete "block" to a complete one. However, the anatomy of the mammalian heart stood in the way of accepting the myogenic theory; it was then generally assumed that in mammals no muscle fibers run between the auricles and ventricles of the heart. That was the situation in 1892. Then came the communication of Kent, made to the English Physiological Society, November 12, 1892, which brought out, among others, these three points: In various mammalian hearts muscle fibers were found to connect the auricles and ventricles; these fibers differed histologically from the other muscle fibers of the heart, and by compressing the tissues between the auricle and ventricle of the mammalian heart by means of a suitable clamp results could be obtained exactly similar to those which were obtained by Gaskell in amphibian hearts. This communication apparently removed all obstacles to the generalization of the myogenic theory. In the years which followed this communication and that of His, Jr., a great amount of work was done on this subject; the main facts were confirmed, many particulars were elucidated and rectified, and finer methods of experimentation were devised—as is invariably the case in the history of all branches of science. From the details of this progress may be singled out for our purpose the facts that the fibers run in a bundle in the septum and that this bundle can now be compressed in a nearly isolated state. Now, on account of the last-named details, Dr. Erlanger insists that Kent deserves no special credit for his work and that his name should not even be mentioned when dealing with the experimental side of this line of work, a suggestion actually carried out by him and other writers. I must emphatically say that, even if the underlying facts were correct, this attitude is neither fair nor just. It is like denying Schwan the right to the discovery of the animal cell because he did not know what protoplasm was, did not understand the meaning of the nucleus, and was wrong regarding the existence of a membrane in animal cells. Moreover, His, Retzer, and Braeunig were wrong in their insistence that there were no histological differences between the conducting fibers and the normal muscle fibers of the heart (and Kent was right on this very important point); nevertheless, nobody would think, on account of this error of observation, of depriving His of the great credit which is justly due him.

But aside from these general grounds I cannot agree with Dr. Erlanger in his destructive criticism of Kent's work, as well as regards some other statements and implications which he makes in his letter. Dr. Erlanger insists that the full report of Kent's work does not indicate that this investigator has even seen the auriculoventricular bundle in the septum, and makes this point the chief basis for his attitude. In judging Kent's paper one ought to bear in mind that the importance of the contrast between the septum and other parts of the auricle was only brought out sharply in recent years by younger writers, and that at the time when Kent made his investigation the general interest was essentially centered in the main demonstration that connecting muscle fibers exist in the mammalian heart, but their exact topography was not yet raised to the dignity of a special problem. In the entire paper of Kent the tendency is in evidence to prove that such connecting fibers undoubtedly do exist, and little interest is manifested in their exact location. The term septum as contrasting with the rest of the heart occurs therefore only a few times in the article. Nevertheless, a careful reading of the article will make it perfectly evident that Kent has seen a well-defined "bundle" of muscle fibers and seen it essentially in locations corresponding to the auriculoventricular septum. The following quotations from his paper will illustrate it. In speaking of the hearts of newly born rats Kent[2] says first that "the fibers being quite continuous and streaming through at the junction of auricle and ventricles as a *strand of considerable size.*"* Later (on same page) he says at "the upper part of the ventricle and in the angle formed by the auricular wall the muscular fibers of the ventricle are seen to have a direction somewhat different to that taken by the auricular, but at about *the center of the isthmus** the auricular fibers are seen to sweep freely down into the substance of the ventricular wall, and the other fibers are to be observed coursing from the auricle into the basal part of the valve." *A strand which runs in the center of the isthmus* corresponds fairly well to the "bundle" in the septum, and the statement that some fibers terminate in the basal part of the valve agrees with the description of His. In speaking of the adult heart Kent says (*loc. cit.* p. 241) that "a *strongly marked band* of muscular tissue remains." Later (on same page), when speaking of the muscle fibers within the septum, he states the following in a separate paragraph: "In the case of the junction between septum ventriculorum and the auricle the fibrous tissue of the base of the valve penetrates a comparatively short way into the muscle and in deeper parts the (muscle) fibers sweep uninter-

*Italics mine.

ruptedly through from auricle to ventricle." *A band of fibers in the septum which sweeps uninterruptedly from auricle to ventricle* is simply the auriculoventricular bundle. There can be no doubt that Kent saw and described the band or bundle of the atrioventricular conducting fibers within the septum.

It is, however, true that Kent apparently claims to have seen connecting muscle fibers also in parts outside of the septum and that some investigators, Tawara, for instance, could not confirm this statement. Dr. Erlanger, however, is not entirely correct in quoting Retzer against this claim of Kent. Retzer's article contains a paragraph which rather supports that claim to a degree. On page 10 of his article[4] Retzer states that it is often impossible to exclude the presence of single fibers or small, indefinite bundles of fibers in the atrioventricular groove, so closely do the muscle fibers come to one another. The histologists have not yet said the last word on this point, which, by the way, is not of fundamental importance.

As to the experimental evidence, I cannot agree with Dr. Erlanger that the complete dissociation of the rhythm of the auricle and ventricle after a complete destruction or compression of the isolated atrioventricular bundle is conclusive evidence that there are no other connecting fibers besides those of the bundle. This result is only a proof that if there are other fibers they are insufficient to keep up the normal rhythm. The death of an animal which follows after the removal of three-fourths of the lungs is no proof that there was no fourth part; it proves only that one-fourth of a lung cannot keep up life.

As to Dr. Erlanger's statement that there was in principle practically no difference between the previous experiments of Wooldridge, Tigerstedt, and Krehl and Romberg on the one hand, and the experiments of Kent on the other. I again cannot agree with him; there is this definite and important difference: the other authors obtained complete dissociation by abrupt *destruction of the connecting tissues;* Kent obtained in *addition all the phases of incomplete dissociation by gradual compression,* a feature which made Dr. Erlanger's experiments interesting and instructive. But, assuming even that Kent's experiments were not different from those of Wooldridge and Tigerstedt, etc., why should Dr. Erlanger quote (in his paper in the *Journal of Experimental Medicine*) these authors and not mention Kent? That others did the same does not attenuate the injustice done to Kent. There is one point on which I fully agree with Dr. Erlanger, and that is that Kent's report of his experimental work is extremely brief, too brief to be of any essential benefit to other investigators. This brevity was greatly to Kent's disadvantage, but certainly not to his discredit; the mental and moral strength to state important facts in a few terse lines is not given to many.

My impression is that very few have read Kent's article and perhaps none with fairness. It is true that regarding the histological side of his work he is often mentioned, but my impression is that it was done in the familiar way; one writer copied from another, who also copied from a previous writer, and so on. It is amusing to find that some writers made two investigators of him, Stanley and Kent. It was the fact that all writers refer to Kent's histological work and that none mentioned his pioneer experimental work, that impelled me to call attention to the latter, without the slightest intention to deprive Dr. Erlanger of any credit which is his. I have to state, however, that meanwhile I have found out that I have no priority right to this discovery. In a book on the "Therapeutics of the Circulation," by Sir Lauder Brunton, published in 1908, I find on page 35 that the credit for clamping the mammalian heart is given in the first place to Kent and in the second place to Erlanger. While this may be historically correct, Kent's brief statement can in no way be compared with the superior work of Erlanger.

I stated in my address that I did not know who Kent is and whether he is alive. Dr. James Mackenzie informed me that Dr. Stanley Kent is professor of physiology in Bristol, England. Perhaps he will feel inclined to fight his own battles.

Before concluding I wish to append two brief remarks indicating the present direction of the cardiogenetic currents. It will be remembered that Retzer could not find that the conducting fibers differed in their histological character from the normal cardiac muscle fibers, and that the bundle contained no nerves. The last statement was, of course, hailed with delight by my friend Dr. Erlanger, who is a stanch myogenist. Retzer carried out the mentioned work under Spalteholz in Leipzig, in the same laboratory where His, Jr., discovered his bundle. Dr. Retzer is now in the anatomical department of the Johns Hopkins University. He still works on the sinoventricular conducting system, as he now terms the old bundle. But what a change in his views! The conducting system he considers now as a neuromuscular apparatus, the sympathetic ganglia, he states, lie immediately above the conducting system, and he is looking for its connection with the ganglia. The Purkinje fibers, the terminations of the conducting system, Retzer states, are surrounded by a plexus of nonmedullated nerves[5]. That looks positively like desertion from the myogenic camp. There is one case of flagrant rebellion. Engelmann, one of the chief founders of the myogenic theory, died recently, and Nicolai, his former chief assistant, who is now himself an authority on cardiac physiology, recently came out very flatly against the myogenic and in favor of the purest neurogenic theory[5]. Furthermore, Trendelenburg[6], who gave at the recent meeting of the German Physiological Society a detailed description of the bundle in various animals, took special pains to declare that, in spite of the bundle, he is not a myogenist; there are too many nerves around the muscle fibers in the bundle[7]. Is the myogenic ship sinking?

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYALTY AT THE HOSPITAL FOR THE PARALYZED AND EPILEPTIC—ROYAL SOCIETY—SLEEPING SICKNESS—ROYAL SOCIETY OF MEDICINE, CHILDREN'S SECTION—GYNECOLOGICAL SECTION—ROYAL COLLEGE OF PHYSICIANS—ROYAL UNIVERSITY OF IRELAND CLOSES—OBITUARY.

London, November 5, 1909.

The King went yesterday to the National Hospital for the Paralyzed and Epileptic and opened the buildings which have been enlarged to celebrate the jubilee of the institution. As Prince of Wales, His Majesty, in 1885, opened this hospital, which was started at the suggestion of the Duke of Albany, and on his decease became a memorial of him. In replying to the address presented, the King referred to that visit, and said he knew and appreciated the work done during the fifty years that have passed since, and was convinced it would be carried on even more efficiently in the improved buildings. After the ceremony His Majesty conferred a knighthood on the chairman of the board of management and went around one of the wards and spoke to the patients, whose cases were explained by Sir W. Gowers.

On Tuesday the Duchess of Albany, as president of the jubilee fund, attended a service of thanksgiving, which was held in the chapel of the hospital, as a part of the jubilee celebration. The Archbishop of Canterbury preached on this occasion, and after the service the Duchess attended in the hall to receive purses for the fund. Those presented contained £150, raising the total received to date to £19,000, which, it is hoped, will shortly reach £50,000.

The new session of the Royal Society opened yesterday afternoon with several papers. One, of medical interest, was by Sir David Bruce and colleagues, and dealt with infection by the glossina palpalis. Sir David is himself absent in Uganda, continuing his work on sleeping sickness. The facts given in his paper appear to confirm the suggestion which has been made, that the infection of the fly may last much longer than has been supposed, as long, in fact, as seventy-five days.

In the section for children's diseases (Royal Society of Medicine) a rare case was shown as "congenital hemidystrophy." The child is a year and ten months

old. When only one month old it was noticed that the left side of the tongue was larger than the right, and later asymmetry of the abdomen was observed. This seems progressive, as at present there is a marked difference between the two sides of the body. Mr. Mummery said he showed a similar case two years ago. As a progressive condition it seemed likely to lead to great deformity. Dr. Parkes-Weber regarded it as hemihypertrophy of muscular origin.

Dr. Wynter showed a case of chloroma in a girl, aged three years and four months, with very marked facial deformity observed since May. The face is large, bony, with skin tense and shiny over malar bones and ophthalmia, more marked on the right. Neck glands enlarged. Red corpuscles, 3,630,000; white, 30,000; hemoglobin, 56 per cent.; lymphatics, 66.2. Members asked how few secondary tumors of the suprarenal capsule had been considered, whether the diagnosis of lymphatic leukemia had been weighed, and how far the blood count was to be held decisive. One mentioned a similar case in a child with sarcoma of the suprarenals.

A specimen of acute inflammation of the appendix was shown in which it had completely involuted into the cecum and so formed the apex of an intussusception. It was removed by operation, and the patient, a girl of eight years of age, made a good recovery.

Dr. Dingwall-Fordyce reported three cases of liver affection in childhood, with notes on the pathology of some conditions. Case 1. A girl of seven had subacute yellow atrophy. A year ago had jaundice, with pain on left side. Seven weeks before death abdomen swelled, diarrhea, vomiting, edema of back, paresis of left leg and side of face, with squint. Temperature, 99° Fahrenheit; pulse, 144. Post mortem showed signs of pleurisy and pericarditis. There was blood-stained fluid in peritoneal cavity, dilated stomach, and in ascending colon an acute tuberculous ulcer. Liver greatly reduced in size and almost flat, its surface irregular, with yellow nodules. Under microscope yellow areas of hyperplasia and much fibrous tissue. Case 2. A girl of eight, with caries of dorsal spine. Died of persistent vomiting a few days after admission. Post mortem showed fatty liver, which weighed 460 grams. Case 3. A boy, aged four years and eight months. First seen for digestive troubles, and liver observed to be enlarged. Died after an operation, which revealed malignant disease of liver, which post mortem weighed 4½ pounds, and was studded throughout with new growth. There was also a tumor in the ileum and the kidneys were enlarged.

Dr. Walter Carr related a case of pneumococcal infection similating general tuberculosis in a child of fifteen months. At first considered pneumonia. The condition continuing for weeks, it was thought later to be tuberculous. Post mortem gave no trace of tubercle, but general pneumococcal infection and pericarditis. The lungs were adherent; in one lobe there was old unresolved pneumonia. About a pint of semipurulent fluid was in the peritoneal cavity. Dr. Sutherland remarked that this was a very unusual case.

In the Obstetrical and Gynecological Section two subjects were pretty fully debated, viz., indications for electrotherapy and cesarean section in placenta prævia. The first paper was by Dr. Curtis Webb, who dwelt on the types of current to use, the methods of obtaining and controlling them, and the treatment of different diseases. Drs. Spanton, Routh, Stedman and Humphries related their experiences with the method, and the president (Dr. Macnaughton-Jones) summed up the discussion. He said there were things to "learn and unlearn," as Goodell had taught him, practices we had followed that had to be abandoned and others we had despised, but afterward had to accept. In the matter before them ignorance of the nature of electricity and of how the different currents operated had for a long time produced suspicion in many minds. Charles Routh and Cutter in the sixties had advocated electricity, and were followed by Tripier, and after him by Apostoli. He had himself used the several methods soon after. He had abandoned the high-tension battery on account of an unfortunate result in a case in which he used it in the manner advised by Apostoli. But the president went on to say the discussion had turned more on cataphoresis and ionic medication as to which he could not offer personal experience. But he had no doubt from the reports of others that benefit had often resulted. He agreed with Dr. Routh that there were cases in which this treatment might be disastrous when more active measures were necessary. He could not agree that curetting removed only the mucous membrane. It certainly affected the underlying muscular tissue and set up a new circulatory relation between the uterus and the adnexa through the blood vessels and lymphatics. He referred to thorough curetting, and at times tamponading—not to mere superficial scraping. The one important point in deciding on electrical treatment, as on other methods, too, was diagnosis, as many had strongly emphasized. In many adnexal cases electricity was not only useless, as, *e.g.* in pyosalpinx, but very dangerous, and that not merely from delay, but from the nature of the interference itself.

The second discussion in the section was based on a case of placenta prævia reported by Dr. Munro Kerr, in which cesarean section was performed. The patient was twenty-eight, one week from term; had been curetted for fibroids and much benefited thereby, and soon became pregnant. A few weeks before term repeated hemorrhages occurred, and examination under an anesthetic revealed a centrally placed placenta prævia and the fibroids on the fundus increased in size. It was thought cesarean section afforded the best chance for mother and child. It was accordingly done, the placenta and living child removed, and then the uterus by supravaginal amputation. A number of fibroids, the largest the size of the closed fist, were on the uterus. Dr. Kerr discussed the question whether cesarean section would not in some cases give a lower mortality than craniotomy followed by version. He thought it would, for he knew nothing more likely to be followed by death or grave septic mischief than a difficult extraction with placenta prævia.

Sir William Smyly congratulated Dr. Kerr upon his success and said his treatment was certainly the best for the case. Both the conditions demanded relief and it involved less risk to treat them simultaneously.

Dr. Griffith also considered cesarean section the best for some cases and related a case in which he had successfully resorted to it.

The president also considered that the operation was indicated in Dr. Kerr's case by the complication with myomata, and mentioned that the question of cesarean section in placenta prævia generally had recently given rise to a most important discussion at the McDowell centennial anniversary.

The Royal College of Physicians has awarded the Weber-Parkes prize and silver medal to Professor Camac Wilkinson, lecturer on medicine at the University of Sydney, and a similar medal to Dr. A. Conyers Inman, of the Brompton Hospital, the essayist next in order of merit. This prize was founded in 1895 by Sir Hermann Weber in memory of the late Dr. E. A. Parkes, and is awarded every third year for the best essay on tuberculosis (prevention, pathology, or treatment), with special reference to pulmonary consumption in man.

On Tuesday the Bradshaw lecture was delivered at the college by Professor J. A. Lindsay, who took for his subject "Darwinism and Medicine." Yesterday Sir T. C. Allbutt gave his first Fitz-Patrick lecture, subject "Greek Medicine in Rome."

Dr. E. W. Hope, Medical Officer of Health for Liverpool, addressed the Association of Public Vaccinators on Friday and said we had learned much from Germany, where both primary and secondary vaccination were compulsory and were rigorously and efficiently carried out. Germany's frontiers were more difficult to defend from an incursion of smallpox than our own seaports, and yet with a population nearly double that of England there were only 600 deaths from smallpox during a recent period of twelve years. During the same period there were in England and Wales 6,761 deaths—more than eleven times the number.

The Royal University of Ireland was dissolved on the last day of October, under the act of last year Sir Christopher Nixon, Vice-Chancellor, delivered a valedictory address. Honorary degrees were conferred on the 20th upon members of the Senate who had not previously received them.

Dr. John Perivale Waggett died suddenly on November 2 at Bournemouth, to which he retired some twenty-five years ago, after a long and active professional life in Kensington. He was in his ninety-first year. He took M.R.C.S. in 1841, M.D. Edin. 1842, and contributed "Observations on Cholera" to the Government report, 1855.

Dr. William Andrew Hayes, P.M.O. Mafeking, during the siege, has died there at the age of forty-eight. He was surgeon-lieutenant in the Bechuava Rifles and medical officer on the Cape Government railways.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

RETURN OF THE CHOLERA—INFECTION THROUGH FISH—CHOLERA CARRIERS—LESSENING SEVERITY OF THE EPIDEMIC—A SUMMARY OF THE CHOLERA SITUATION IN THE PHILIPPINES—SUICIDES—PERSONAL.

MANILA, September 30, 1909.

CHOLERA again made its appearance in the City of Manila during the early days of September. Its exact origin cannot be definitely stated. As in previous years, however, a few deaths occurred from time to time during the preceding two months among persons who had some of the clinical symptoms of the disease, but cultures taken before and after death were negative for cholera. On post mortem the gross lesions were found to be moderately injected small intestines, which did not contain the characteristic rice-water like contents. The principal lesion was found to be an intense acute parenchymatous nephritis. The cases invariably had supression of urine before death, which is one of the most constant clinical symptoms of cholera. Investigations made recently indicate that in some of these cases a spirillum can be obtained directly from the heart's blood. Whether there is any connection between the suspicious cases which occur before the appearance of the annual outbreaks of true cholera in Manila during the past few years is, of course, not known as yet.

The outbreak this year might be due to the introduction of infected fish from the nearby province of Bulacan, which has been badly infected with cholera, and from which there are large daily importations of this foodstuff. If the fish should have been the cause, the Bureau of Health believes that it was purely a surface infection and that the disease was directly contracted through handling them before they were cooked.

It is also worthy of notice that coincidently with the appearance of cholera there were "cholera carriers" found who were harboring in their intestines virulent cholera vibrios without having any symptoms of the disease and being apparently in good health. A house-to-house inspection in the City of Manila was already in force before the appearance of cholera, and the cases were so promptly found and isolated and the necessary disinfection done that at no time during the month have there been more than five cases reported for any one day. During September the total number of cases reached 70, among which there were 50 deaths.

Cholera has also finally gained a foothold in the port of Cebu, and it is feared that it will spread throughout the Island of Cebu; and with the dense population of over 700,000 persons, the consequences would likely be serious.

A most encouraging feature in connection with the cholera outbreaks is the fact that only dozens of cases occur now where in the earlier years there were hundreds. This improvement is undoubtedly due to the campaign of education which has so persistently been waged during the past few years.

In the more advanced provinces, like Albay, where there were 352 cases, during the past few months no cases occurred among the public school children. In the province of Ambos Camarines, where there were 569 cases, only one case was contracted by a public school child, while a number of cases occurred among the children attending private schools.

The Director of Health in his Annual Report for the fiscal year ended June 30, 1909, gives the following summary of the cholera situation in the Philippines: "A careful review of the cholera conditions in the Philippines during the past few years, coupled with a study of the cholera reports from the different parts of the world in which the disease exists, leads more and more to the conclusion that the cholera question in the Philippine Islands presents much the same problem as typhoid fever in Europe and America. The experience of the Bureau has demonstrated again and again that the disease can be controlled and that those who desire to take the few simple precautions which all residents of the tropics should take in order to protect themselves against intestinal diseases, can rest assured that they will not contract the disease. The prospects of lessening the number of cases each year are excellent, and its complete eradication is not too much to hope for because many brilliant scientific men with liberal endowments to aid them are at present at work in all civilized countries seeking to perfect measures for eradicating typhoid; and when these are found, they can likewise be applied to cholera, and this scourge removed from our midst."

Figures have just been compiled giving the number of cases of suicide in the Philippine Islands during the past five years. The report shows that there were 1,386 cases reported. This would mean that the average number per year is about 4 per hundred thousand of the population; this is exceedingly low when it is remembered that the number of cases in the United States reaches at least 14 per hundred thousand. This is a most striking difference, and offers considerable opportunity for speculation upon the cause for so great a difference between the Occident and the Orient.

Dr. Alexander Rochester, who has been connected with the Bureau of Health during the past three years, has resigned his position and will engage in private practice at Columbus, Ohio.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 11, 1909

Vaccine Treatment of Lobar Pneumonia.—T. Leary refers to recent literature and reports on this mode of therapy and passes on to consider the results of 34 cases either alcoholic or of an extreme type. Pneumococcus vaccine was given and all but 6 recovered. In a larger series (49) of ordinary cases, 15 per cent. came to a crisis in 3 days and all but 2 recovered. The total deaths in the 83 cases were 8 or 9.7 per cent. He considers the results sufficiently encouraging to justify a wider application of the treatment. There was a rapid relief of toxemic conditions which were present in the serious cases and in those with uncontrollable delirium, an abatement of this symptom was prominent. He adds that in his experience the use of the opsonic index has very little value for controlling treatment of acute infections. In acute conditions also, with proper dosage of vaccines, the negative phase is either harmless or ephemeral. He has shortened the intervals between injections, in acute general infections, to four-hour periods, using smaller doses, and his results have been good. As to the time of exposure of suspensions of bacteria to heat for the purpose of killing, he finds fifteen minutes to be the most desirable. In giving vaccines, the patient plays an active part in the process and if success is to be obtained he must have sufficient resisting ability to react under the stimulation of the vaccine. Vaccines in moribund patients are, therefore, useless. The dose of the stock solution in pneumonia is 8 minims. The bottle should be kept in a cool place and the contents used promptly. They are made from typical sputum sent into the laboratory. From such a specimen an autogenous vaccine can usually be made in twenty-four hours.

The Physiological Aspects of Gastroenterostomy.—W. B. Cannon says that according to physiological observations, there is no alteration of peristalsis because a new opening is made midway in the stomach. The notion which has been expressed by some surgeons that such an opening gives the part of the stomach beyond its rest from activity is quite erroneous. If the pylorus is not obstructed this continued peristalsis results in forcing food through the normal opening at the pylorus. The psysiologist has difficulty in seeing any advantage gained by this operation unless the passage of the bile and pancreatic juice into the stomach reduces hyperacidity. Experienced surgeons now advise against the operation unless the pylorus is obstructed. If obstruction is present, food leaves the stomach through the artificial opening and though the acid chyme doubtless causes a flow of pancreatic juice and bile, it may not receive a proper admixture of these fluids. As a consequence a considerable amount of fat and the protein of the food may pass through the alimentary canal without being absorbed.

New York Medical Journal, November 13, 1909

Pityriasis Rosea with Pseudo Vesicles.—U. J. Wile comments on the occasional difficulty in diagnosis between this condition and psoriasis and seborrhoic eczema and narrates the history of the case of a woman whose body from head to feet, extending even down to the fingers, and excepting only the scalp, was covered with a profuse, distinctly raised, yellowish red, and at first sight seemingly papular eruption. The individual lesions varied in size from a pinhead up to a ten-cent piece, and for the most part they were oval or round in shape. Examined closely, the lesions showed very distinct differences in their structures the smaller ones were indeed papules, but the larger ones having a more distinct yellowish hue seemed to be papules superimposed upon deep-seated vesicles. When such were punctured with a needle a

drop or two of clear serum could be expressed by firm pressure. In the very large lesions the fluid contents were more superficial and in some instances had ruptured to the surface, and in drying had given rise to crusts and scabs. The mucous membrane of the mouth was entirely normal, but at the anal orifice and within the vulva were numerous small ruptured and unruptured vesicles, not herpetic in outline or character. There was further present a marked general lymphadenitis. The patient was treated with soothing lotions, saline purges, and she was placed on a simple rational diet. Within twenty-four hours a marked change in the condition had already taken place; the lesions were much flatter and fewer of the vesicle-like elements were to be seen. A few days more brought about the entire disappearance of the latter, and at this time the patient presented the typical picture of an involuting pityriasis rosea, which went on to a complete cure in about five weeks. The author has not been able to find a similar case on record.

Medical Charity.—L. H. Schwartz comments on the need of the establishment throughout the city of stations where prescriptions for poor people can be filled at a moderate rate and where they procure sick-room requisites or can secure them on loan when ordered by the physician. He says that medical charity has been abused to an unusual degree during the last two years. There are several causes for this. First, the classes at dispensaries are too large so that the physician has no time to inquire into the circumstances of the patient. Second, some institutions do not want, for selfish reasons, to cut down their attendance. Third, the large dispensaries hold out such inducements in way of equipment that many people are attracted away from the family physician. Fourth, some physicians send their patients to the dispensaries in order to get a diagnosis free from the professors in charge. Fifth, very many people who go to the family physician for ordinary ills go to the dispensary when they want special treatment. Sixth, many plead hard times while they are abundantly able to pay. Seventh, the usual custom of dispensaries in charging a small fee for medicines, dressings, etc., makes the patients feel that they are paying for what they get and are not asking charity. Two plans for reform present themselves. The first method is this: A patient applying at a dispensary should receive treatment for the day on which he applies. A card should be given him stating that before he can again get treatment he must go to the Department of Public Charities to report and record his case for investigation. It would not be necessary to investigate every case and this work could properly be delegated to the Department of Public Charities and Correction. The district attorney's office should be required to prosecute those who obtain medical or surgical aid under false representations. The mere fact that they must report to the Department of Charities would keep 90 per cent. of the fakirs out.

The Technique of Orcheopexy.—This subject is discussed in an elaborate illustrated paper by F. Torek, who says that recently he has been treating cases of nondescended testicle by attaching the testis to the fascia of the thigh. He acknowledges the similarity of the method to that of Keetley, although his own method was developed independently and without the knowledge of Keetley's. His own plan differs in some essential points. Keetley recommends dividing the cremaster as high up as possible and turning it down in order to attach the cremaster and not the testis itself to the thigh fascia. Torek attaches the testis itself and finds that it hangs normally in the scrotum, whereas Keetley admits that in some instances the testis was placed in the pubic region, where it might be injured. Space does not allow us to go into all the details of Keetley's operation. His paper is fully illustrated and must be read by those interested. In cases of bilateral retention only one testis is brought down at a time, as in those cases the scrotum is rudimentary and could not be fastened to both thighs without considerable tension. In all of Torek's cases success has been complete. In the description of the operation the author lays stress on exactness in suturing, as he considers this to be an important factor towards insuring primary healing without local irritation. In none of his cases has there been the slightest reaction in a stitch canal. In all cases the testis was at the bottom of the scrotum and in all it has increased in size. He admits that his technique is more difficult than in other procedures, but says that his efforts have been amply recompensed by the completeness of his success.

Some New Fields and Methods in Psychology.—F. Peterson says that in time past phychology has seemed to him a barren field of work. Academic psychologists have made the subject very unattractive. He refers to the modern use of the word "unconsciously" as suggesting a fascinating domain, viz., unconscious, coconscious, subconscious and the subliminal conscious. For instance, each man's vocabulary, be it large or small, is related to all subconscious material. A word has a magic power in it to summon from the vaults of memory all sorts of apparitions. The modern method of psychanalysis has been developed by Freud, whose technic of performing it is described. The object of such psychanalysis is twofold. In the first place we uncover the details of some psychic trauma which is usually at the basis of all hysterical manifestations and of many psychoneurotic conditions such as obsessions, phobias, and the like, and may be the origin of some type of insanity like dementia præcox. In the second place, it is a therapeutic procedure and the analysis generally cures the patient. The views of Freud on dreams are interesting. They always seem to be the fulfillment of some wish or desire. The child receives in dreams the delights that he longs for. When a dream is recorded and examined we have before us a curious piece of conglomerate, often uniting materials from the days of childhood with experiences of yesterday, full of absurd distortions of events and words, transformations, allegories, and symbols. There is nothing accidental in the arrangement, and by psychanalysis of the person having the dream one determines the origin of every patch in the crazy-quilt, and by investigation one discovers the wish at the foundation which is directly or indirectly fulfilled by the dream. Freud has been much criticized because in his opinion it is usually a sexual idea which is the fons et origin of these dreams as well of hysteria and other psychoneuroses. He is, perhaps, extreme in this opinion, but we might grant him half, since, roughly speaking, fifty per cent. of trends, wishes, desires that inspire our activities, are for the perpetuation of the species and fifty per cent. for self preservation.

Journal of the American Medical Association, November 13, 1909.

Treatment of Idiopathic Multiple Hemorrhagic Sarcoma.—H. J. F. Wallhauser reports two cases in which he has successfully employed bichloride of mercury solution in this disease. A solution of bichloride of mercury, one or two thousand, was applied in the first case to overcome the offensive discharge. After several weeks however, it was noticed that the larger tumors had perceptibly diminished and that several small pea-sized tumors had altogether disappeared. The strength of the solution was then gradually increased to one to five hundred and applied in wet compresses. At the end of four months all growths had disappeared and the patient was seen two years later in good health with no recurrence of the disorder. In the second patient, after cutting off the larger masses the same treatment was applied and continued for about six weeks when all the wounds had cicatrized and the smaller unexcised tumors were decreasing. With the gradual increase to 1 to 500 strength of the solution a slight dermatitis developed and the milder solution was substituted. All lesions had disappeared at the end of six months, leaving only the increased pigmentation and a few areas of white slightly atrophic spots, the skin appearing otherwise normal. The patient, a woman, was later admitted for alcoholism and still later again, nearly three years after the first treatment, for a new growth in another region, of the same general character which, according to her statements, appeared about six months previous to this admission. There was only one tumor on the inner side of the thigh which was stiff, swollen, and very painful, the slightest movement causing acute lancinating pain. Treatment to improve her general health, which was bad, was instituted, but she never rallied and died in coma a few weeks after her admission to the hospital, of a complication of conditions as shown by the post mortem. Wallhauser remarks on these cases that from a study of the histopathology the exact nature of the condition still seems dubious. It is generally accepted that it is of vessel origin and that the vessels play an important part in its production. This is borne out in the examination of these two cases. Whether it is sarcomatous or granulomatous is also in question, authorities holding both opinions, while a few recently place it midway between the two, and the author seems to think this the best solution of the problem at the present time. From these two cases he assumes that it cannot be considered necessarily a fatal disease. The slow progress of recession of lesions would certainly point to a favorable issue as compared with the rapid growth and gland involvement of sarcoma.

Tropical Medicine.—J. A. Nydegger points out the advantages derived from the establishment of the British schools of tropical medicine, and pleads for the foundation of a similar institution in this country. With our increasing intercourse wtih tropical regions and acquisition of tropical dependencies, and with the greatly increased amount of travel in such regions by our citizens, the need of such an institution is becoming more and more apparent. We have courses in tropical medicine in some of our schools but they consist chiefly of a few optionally attended lectures, often given by instructors who have not seen tropical diseases, or if so, only to a limited extent, and, therefore, whose lectures could not be conducive to the stimulation of a lively interest, so necessary on the part of the student. The army and navy medical schools and the Hygienic Laboratory of the Public Health and Marine-Hospital Service give courses of lectures on tropical medicine, but it is only one of the subjects studied and the courses are not generally available to the civil practitioner. Until a special school is established there will be no place for the special study of these diseases for the medical practitioner in those parts of our country where these diseases are liable to occur, or who as medical missionaries or otherwise may wish to settle in tropical regions.

Urinary Findings in Children.—W. L. Carr says that when careful routine examinations of the urine are made in all diseases incident to childhood more kidney complications will be found than are at present commonly observed. The diseases in which urine examination is often omitted are gastroenteric disorders, influenza, tonsillitis, and conditions of defective metabolism. Under the term gastroenteric he includes all the disorders of digestion and not merely the summer complaints, and he quotes from various authorities, Chapin, Mason Knox and Meakins, Herter and others in support of his views. While the testimony seems to indicate that the majority of children who have albumin and hyaline casts in these diseases recover, this belief in recovery is largely based on ignorance of the state of the kidney for the period following the acute disease. He urges a routine examination and the following up of the case for months or possibly years after the subsidence of the acute symptoms to trace the presence of kidney defects. In closing he calls attention to the need of more study of the centrifuged sediment of urine as it may contain casts even if the urine has not shown the presence of albumin.

Mistakes in Diagnosis.—J. P. Crozer Griffith reports several cases in children in which, after an injury, symptoms appeared which might be, and were in some cases, attributed to this as a cause, whereas in reality the trauma and the disease causing the symptoms were simply coincident. In one case the examination of the blood revealed cerebrospinal fever, causing symptoms which were observed immediately after a fall from a street car. Another child was kicked in a fight and later went into an unconscious condition with convulsions and temporary hemiplegia which disappeared without any treatment to account for it. A somewhat similar case was also reported in which a child was said to have been hit by a street car. In still another suffocation from ingested matter was suspected, and it is quoted particularly as an illustration of the possibility of error from leading questions given to parents and friends who are open to suggestion. The choking of the child was elicited by the physician in questioning the parents, but the case was one of retroesophageal abscess, as shown by the autopsy. Perhaps one of the most misleading diseases, the author says, is infantile scurvy, and he has repeatedly seen the sudden development of pain in the limb from this disease attributed to trauma. Two cases are reported. Griffith says he might multiply such cases from his experience, but these he thinks will be sufficient as striking examples of the necessity of caution in the diagnosis of any supposed injury especially in children.

Spinal Cord Lesions from Pasteur Treatment.—W. A. Jones reports two cases of spinal cord symptoms following the Pasteur treatment and the notes of two similar cases obtained from other sources. The symptoms are not unlike those of Landry's paralysis or severe multiple neuritis, and it is notable that they began in the neighborhood of the point of inoculation and spread from there to other parts of the body, indicating that, like the rabic infection, the toxin travels along the nerve tracts to the spinal cord where, probably, it sets up a myelitis. The prognosis, however, is usually favorable, though one of the cases reported terminated fatally. Similar cases have been reported by European authorities and those reported by the author make sixty-two thus far recorded in the literature, and with the two added in his note from other sources, sixty-four. Letters sent to thirteen Pasteur institutes in this country asking for information concerning similar cases, brought reports of no others, though nine responded. It seems to be recognized, however, by some foreign authors that such symptoms appear in a certain proportion of cases treated by the Pasteur method. Previous genuine rabic infection does not seem to be necessary for their appearance.

Pellagra, Ancient and Modern.—H. D. King gives an historic sketch of the disease pellagra, showing its spread and increase in the countries where it exists. He accepts the view that it is due to the eating of damaged maize. There seems to be hardly a country in Europe where it is not more or less prevalent with the exception of the northern regions, Italy, France, and Austria seeming to be the greatest sufferers. In Great Britain the disease has been noted but twice and there does not seem to be any record of it in the Scandinavian countries or in northern Russia. In northern Africa it is also very prevalent. On this continent it has been recognized in Brazil, Mexico, and the Argentine Republic as well as in the West Indies. The recent recognition of it in the United States was preceded many years ago in 1864 by the reports of two or three cases at which time also a small outbreak was noted in Nova Scotia. Reports of this are very meager and uncertain. It is noticed as remarkable that the medical records of the Civil War contain no mention of pellagra, but King suggests that it may have existed unrecognized in the southern prison camps and he suggests further inquiries as to this point as a profitable subject for investigation.

The Lancet, November 6, 1909.

Lung Puncture: a New Application of Clinical Pathology.—T. J. Horder says that diagnostic puncture of the lung may be made under two conditions; (1) a pleural effusion is suspected in the pleural sac and the result of the puncture negatives this, and (2) no fluid is suspected, but the lung is deliberately punctured for the express purpose of discovering the nature of the process within the lung itself. The procedure is indicated in any case, yielding signs of consolidation of the lung in which careful examination of the sputa fails to reveal the nature of the disease. The puncture will frequently yield evidence of a mixed infection as influenza bacillus and pneumococcus. (2) In abscess it is useful to obtain a specimen of pus from the actual site of suppuration, for thereby we obtain a specimen of the causal bacterium, which, if often a matter of great difficulty when dealing with sputum alone and (3) in bronchiectases, the same thing is true, for the flora of the sputa is notoriously varied and difficult of interpretation. We should be careful to make our punctures under strict antisepsis, avoid dangerous areas, and not go deeper than one inch. The method of handling the material withdrawn will depend on its amount. It may be used for culture purposes alone or be employed to make films, which may be stained and examined in the usual way. Six illustrative cases are recorded. The author has made puncture 14 times. In view of the modern tendency to vaccine therapy, it often becomes necessary to find out just what organism is at the bottom of the pathological process in order to prepare the vaccine intelligently.

The Dyspepsia of Old Age.—W. S. Fenwick finds that out of 100 persons over 65 years of age suffering with chronic dyspepsia, 66 of the cases are secondary to organic disease of some important bodily organ, while 34 owe their symptoms to a progressive degeneration of the secretary structures of the stomach and bowel. In the former class the digestive disorders usually take the form of a chronic gastritis, due to disease of the kidneys, prostate, heart, lungs, liver, pancreas, chronic gout, or inefficient mastication; while about ten per cent. of the entire number are due to long-continued hypersecretion from chronic ulcer in the vicinity of the pylorus, gallstones, or diseased appendix. The pathological changes are traced, and are found to be more constant in women. Flatulence is the most constant symptom of the complaint. It is particularly severe at night. Constipation alternates with diarrhea. The main indications for treatment are to correct the subacidity and to relieve the flatulency and constipation. Large doses of diluted HCl may be given twice a day after meals, combined with a dram and a half of glycerin. Pepsin is useless. Metchnikoff's sour milk is undoubtedly one of the best means of relief. Malt preparations are of service when the intestine is particularly at fault. The usual bitter tonics had best be omitted, as they are apt to aggravate the condition. The new alcoholic essence of peppermint is of great service. One teaspoonful may be

given in a sherry glass of water for an acute flatulent condition. For the constipation salines and mineral waters are to be avoided and recourse had to a mixture of cascara and maltine, a confection of sulphur and guaias, an infusion of senna pods or to an occasional dose of gray powder.

Sinusitis Occurring as a Concomitant Complication of Influenza.—According to R. M. Manwarring-White, the association of the two diseases is very common. Owing to the direction of the major air stream, the frontal sinus is apt to be involved more often than any other. The symptoms are detailed and the author's account contains nothing new. They usually continue for one to two weeks and gradually subside. The regularity of the pain coming on as it does about 10 a. m., lasting till about 3 p. m., and then disappearing till next day, is a usual feature of the malady. When the sphenoidal sinus is involved there may be a marked somnolence; when we realize how near to important structures at the base of the brain the sinus is situated, we can easily account for the anxious symptoms which may ensue. There is usually conjunctivitis and edema of the lid and vision may be affected. Optic neuritis and blindness may occur, due to pressure on the optic nerve as it passes through the wall of the sphenoidal sinus. For treatment the author applies hot fomentations over the affected side, and inhalations of oil of eucalyptus menthol and rectified and methylated spirits are given. Cocaine and adrenalin may be used about the middle turbinate. Phenacetin, aspirin, etc., may be given to relieve pain. If the soft tissues over the sinus become red, swollen, edematous, and pit on pressure on external opening may be necessary.

Tertiary Syphilitis Terminating in Sudden Death from Abductor Paralysis of the Vocal Cords.—The patient of R. J. Browne was a man of 30 years without distinct specific history. He had a cough and some dysponea. On simple local and constitutional treatment he improved, but he grew worse raising considerable tenacious mucus. One night he suddenly died while trying to call some one for relief. Autopsy showed the cords in the cadaveric position. They were thickened and there was some scarring, the result of old ulceration extending toward the base of the epiglottis. The trachea was scarred and ulcerated in several places with a gradual narrowing of the lumen. Three inches below the larynx there was a stricture which would just admit a No. 7 bougie. Below this the ulceration and contraction extended down into both bronchi. Near the bifurcation one or two gummatous glands were on the point of breaking down. The author considers the case as one of sudden death due to abductor paralysis. In syphilis localized brain centers are often apt to be involved alone. If in this case this was true the abductor muscles, which are always the first to be affected, were paralyzed, while there was doubtless a spasm of the abductors. The autopsy did not show whether or not the inferior laryngeal nerve was directly involved in the lesion. According to the author abductor laryngeal paralysis is always to be thought of in mysterious cases of sudden death.

British Medical Journal, November 6, 1909.

A Note on Oriental Sore.—R. M. Carter refers to his previous papers on this subject, saying that the term "Oriental sore" is an anomaly as it stands at present, for under this name are grouped several affections of the skin and subcutaneous tissues clinically quite distinct. In North India there is the Monghyr phora, a pale, yellow, painless area from one-fourth to one-half inch square, surrounded by a red margin, usually on the face near the lips or eyes, on the cheek or forehead. It does not break down. It may last for a year, and after healing with a faint scar may recur on other parts of the body, such as the elbows or wrists. Second, there is the Chambal, a large, flat-surfaced ulcer, fairly deep, with a bed of raised papilliform prolongations of the corium which support a mass of epithelial débris. Third, there is the typical Delhi boil. The parasite, described recently by Row from South India, is capsulated and chiefly of an oval type. Row states that each parasite is lodged wtih a clear space in the macrophage. The parasite worked with in North India has no capsule, is almost torpedo-shaped, has no clear space around it, and distends the mononuclear cell it invades, almost to bursting. The rosy-red parasites seen in cultures from patients of Mongyhr phora apparently do not occur in the type of Oriental sore described by Row. They are not described by him, and he does not record flagellated bodies of this type.

A Case of Disseminated Tuberculosis Treated with Marmorek's Serum.—H. Hemsted's patient was a Spanish school boy of 15 years. The chief features of the case were the following: First, repeatedly negative Widal test, though every symptom was consistent with typhoid, which the case was at first thought to be. Second, there seemed no doubt that Marmorek's serum, of which the boy had forty injections, or nearly half a pint, in the course of three months, was responsible for the improvement in the case. The clinical signs pointed to tuberculous lesions of the intestines, peritoneoum, bladder, lungs, and meninges. The author supposes that the invasion was of the miliary type, in which case by all the rules of medicine the patient ought to have died. Temperature reactions commenced about three hours after nearly every injection. It is admitted that the boy may yet become a chronic phthisical case. Inquiry revealed the fact that the right kidney had been previously removed and found tuberculous. The patient when first seen had suffered from hematuria for about six months. The Marmorek serum was of the new variety made from the primitive bacillus obtained from the growing margin of a culture. With this a horse was immunized for about eight months. Injections were made in the patient's thigh of 5 c.c. through a head of lysol. The injections were repeated for twelve consecutive days. In the ensuing seven weeks some twenty-eight injections were administrated. The patient slowly but surely improved. The typhoid condition with its temperature, diarrhea, etc., all disappeared. Evidences of tuberculosis in the lungs gradually subsided, and though the boy had a slightly turbid effusion of the left side, it rapidly disappeared after tapping.

Further Researches into the Bacteriology and Vaccine Therapy of Common Colds.—C. H. Benham refers to his previous communications on this subject and additional experiments made during the last two years. The prevailing organisms he has found during the period have been the *Micrococcus catarrhalis* and the *M. paratetragenus*. The *B. septus* was present in a number of the cases, but it did not grow readily and was difficult to isolate. The *B. Pfeiffer* was present in some cases in small numbers, but it was not possible to isolate it. The pneumococcus was seen in the swabs in a few cases, but in small numbers, and it was not isolated. The *B. Friedlaender* was isolated from a few of the cases. The result of the author's vaccine therapy convince him that in cases of catarrh caused by the *M. catarrhalis* there are marked fluctuations of the opsonic index. Second, that a fall in the opsonic index coincides with an increase in the severity and a rise of the index with a decline in the severity of the symptoms. This is more marked in the acute cases. Third, that a suitable dose of vaccine given at an appropriate time will cause a rise of the opsonic index, which may be preceded by a negative phase of short duration. Fourth, that it is probable that similar fluctuations may occur in the case of the *M. paratetragenus*. No good cultures have thus far been obtained for opsonic work with the *B. septus* and *B. Friedlaender*. In view of the fact that many common colds gradually spread down to the larynx and trachea and may lead to bronchopneumonia, the author thinks this matter of vaccine therapy in the earlier stages one of great importance. The *M. catarrhalis* has been found in healthy noses and throats, in the lungs in acute cases of pneumonia, and in all the organs in a fatal case of pneumotyphus. The *M. paratetragenus* has been found in the blood of a patient who died of pulmonary gangrene and in the pus of a foul empyema.

Berliner klinische Wochenschrift, October 25, 1909.

Childhood Tuberculosis and Immunity.—Ritter and Vehling tabulate a large series of tuberculosis cases in regard to the occurrence of the disease in childhood and exposure to infected members of the family. They state that there are three cardinal points which must be carried out in order to succeed in the fight against tuberculosis. (1) The separation of the bacillus-spreading consumptive from his home and family, in order to prevent the general infection, especially of the children; (2) careful and prolonged treatment of scrofulous and tuberculous children—the difference is only in the grade of the disease—in order to obtain a complete healing of the tuberculosis; (3) stimulation of the weakened immunity element in adult tuberculous patients by single or repeated treatments in sanatoria, in order to prevent the transformation of a hopeful case of tuberculosis into a hopeless progressive consumptive. It is evident that the treatment of tuberculous children as well as adults must follow the lines of the well-known dietetic and hygienic measures. Nevertheless, the treatment by tuberculin, thought it can as yet produce but a partial immunity, must play no small rôle in the treatment.

Münchener medizinische Wochenschrift, October 19 and 26, 1909.

The Influence of Sinusoidal Baths Upon the Heart.—Veiel investigated the action of sinusoidal electric baths upon the heart, and concludes that it acts in a manner similar to the carbonic acid bath. Great care is required in regulating the dose: one cannot follow any rules. The best criterion of the dose is to be found in the patient's feelings. A feeling of fatigue which does not disappear after brief rest is an indication for a weaker current at the next treatment. In the sinusoidal bath we have an addition to balneotherapeutic treatment of the heart which has a definite action without the use of a full bath. Such an active increase of cardiac action as occurs after carbonic baths cannot be obtained. The individual susceptibility to the sinusoidal bath varies more than with the carbonic baths. This form of bath, therefore, has its place when a mild balneological regulation of cardiac power is required, and for one reason or another carbonic baths are contraindicated.

Narcosis with Artificially Decreased Circulation.—Hörmann has studied the effect of reducing the circulatory system by putting Esmarch bandages around the thigh during general anesthesia to reduce the circulation, and has found that his experiments on man agree completely with the animal experiments of Verth and Ziegner. The results of the procedure were a diminished amount of narcotic required, especially with chloroform; a rapid awakening from the narcosis, and the use of this isolated carbonic-acid laden blood to relieve the asphyxia. The contraindication to the procedure are varicose veins and arteriosclerosis.

Amaurosis During Pregnancy.—Himmelheber reports the case of a woman of 34 years of age who during her seventh pregnancy had headache, vomiting, and blindness. She had no convulsion or edema. The urine contained 0.4 per cent. albumin, leucocytes, blood, and all kinds of casts. The ophthalmological examination showed an optic neuritis, retinal hemorrhages, and white patches. After abortion the condition of the urine improved rapidly but the amaurosis continued, with the development of optic atrophy.

Serum Treatment and Its Dangers.—Scheidemandel reports the case of a girl of 19 who was suffering from osteomyelitis of the pelvis. For this an antistreptococcus serum was injected as follows: January 10, 10 cc.; January 14, 10 cc.; January 21, 25 cc.; February 5, 25 cc.; March 12, 5 cc. Immediately after this last injection she complained of pain and dizziness. She sat up in bed suddenly, struggled for breath, vomited, and was markedly cyanosed. Innumerable small hemorrhages appeared on the forehead, neck, and breasts. The breathing stopped and the pulse became very weak. Camphor and caffein overcome the collapse and the patient recovered. At autopsy, three months later following death from the osteomyelitis, there was no sign of hemorrhage in the internal organs. This the author considers to be a typical case of anaphylaxis due to repetitions of the doses of serum. The reaction appears, as a rule, when there is a pause between the first and second injection varying from 10 days to six months. The author asks how such accidents are to be prevented. He calls attention to the fact that in animal experiments injections of calcium chloride and calcium lactate have prevented the appearance of the phenomenon. In every case where serum is to be given it must be ascertained whether or not a previous injection has been made within a few months. This knowledge is not always definitely a safeguard, as cases of hereditary hypersensitiveness have occurred. The best method is always to give a small initial test dose of the serum and then if no symptoms appear to repeat shortly, with gradually increasing doses. Intravenous injections should never be given until the absence of anaphylaxis has been definitely ascertained. The indiscriminate use of all kinds of unproven sera in enormous doses is most strongly to be deprecated.

A New Method of Proof of Proteolytic Ferment and Antiferment.—Mandelbaum refers to the Loeffler's plate method of Müller and Jochmann and the casein method of Gross and Fuld and then describes a new plate method which he believes to be more delicate than either. It is as follows: Two parts of ordinary agar-agar and one part of milk are mixed, heated to 100° C., cooled to 50° C—60° C, well shaken, and poured into Petri dishes, which are gently agitated until the medium has hardened. These plates are then used quite similarly to the Muller and Jochmann plates. The improvement consists in the fact that instead of having to see a minute hollow in the serum where the ferment has produced digestion, the much more evident change takes place of the white medium becoming transparent. This is due to the digestion of the protein covering of the fat and its consequent solution with bars of the white appearance of the emulsion.

Postoperative Duodenal Ileus.—Weinbrenner reports such a case, discusses the condition and summarizes his conclusions as follows. The etiology of past operative duodenal ileus is not entirely clear. The theory that the obstruction occurs only as a secondary condition to an acute gastric dilatation does not hold good. The strangulation may also be primary. Mechanical factors which can cause a dragging on the mesentary may also play a rôle, especially drainage and adhesions. The symptoms may suggest a peritonitis running an acute stormy course, which obscures the diagnosis. To prevent a mistaken diagnosis with possible serious consequences in the differential diagnosis, bile containing post-operative vomiting suggests the duodenal ileus. In therapeutics the placing of the patient on the abdomen or in the knee chest position is of the first importance. In this position the pressure and weight of the small intestine and the stomach acts in a different direction so that the relaxation of the mesentary and the freeing of the duodenum results. Weak mesenteric adhesions may be loosened or relaxed, a possibility which makes it advisable in all forms of post-operative ileus before undertaking a secondary laparotomy to try all possible postures.

The Respirometer.—C. A. Bucklin of Glasgow has devised an instrument to which he has given this name, the purpose of which is to measure the degree of the obstruction of the nostrils to respired air from which he draws conclusions as to the indications for and results of rhinological procedures. It consists of a glass tube 41.5 inches long and ⅜ inch in diameter with a bore of ⅛ inch. To each end of this tube is fitted a stiff piece of rubber tubing 3 inches in length, which extends ⅛ inch beyond the end of the glass tube. A notch ⅛ inch in diameter and ⅛ inch in depth, disposed at right angles to the bore, is burned into the end of each piece of rubber tubing. At 30 inches from each notch is the lower margin of a narrow ring of rubber tubing. These rubber tubings are used for protection and measure indications. To use the respirometer a tumbler containing one-half inch of water is placed upon the floor into which one end of the respirometer is immersed. After complete expiration the patient takes the upper end of the instrument firmly in his mouth, depresses his tongue with it, and makes the strongest, quickest nasal inspiration possible. The height to which the water rises in the tube indicates the degree of vacuum produced in the mouth which is in turn proportional to the nasal obstruction. The instrument is disinfected in a specially made case, as shown with the instrument in the plate. This is of vulcanized rubber, ⅞ inch in diameter, with a bore of ⅝ inch, and a length of 42 inches. The bottom cap is screwed on and cemented, while the top is so adjusted that it may be turned with the fingers. An aqueous solution of bichloride of mercury 1:31.25, made by dissolving two "1:1003" tablets in each fluid ounce of water is put in the case. The tube placed in this for 2 minutes is disinfected. The end is dipped in clean water before use. In hypertrophic nasal catarrh for a satisfactory result, the instrument after operation should register not more than one-half what it did before treatment. A double partial turbinectomy for hay fever or asthma reduces the register to one-fourth of the original. The registration of the instrument is proportional to the attitude. The average height to which the water rises in a case of hypertrophic nasal catarrh is 37 inches. The respirometer is recommended as an indication for operation, an estimation of the results, and for settling disputes on these subjects.—*Archiv fur Laryngologie.* Vol. 22, No. 2, 1909.

Tuberculosis and Poverty.—That poverty is a friend of consumption is demonstrated by some recent German statistics, which show that of 10,000 well-to do persons, 40 annually die of consumption; of the same number only moderately well-to-do, 66; of the same number really poor, 77; and of paupers, 97. According to John Burns, the famous English labor leader, 90 per cent. of the consumptives in London receive charitable relief in their homes.—*Ohio State Medical Journal*

Book Reviews.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. Philadelphia and New York: Lea & Febiger, September 1, 1909.

The present number contains contributions on Diseases of the Thorax and Its Viscera, including the heart, lungs, and blood-vessels, by W. Ewart; Dermatology and Syphilis, by W. S. Gottheil; Obstetrics, by E. P. Davis, and Diseases of the Nervous System, by W. G. Spiller. These various departments of medical science are well and thoroughly reviewed. Of particular interest are the forty pages devoted to tuberculosis, and the sixty pages dealing with pregnancy and its complications. This publication continues to give the busy practitioner an authoritative summary of all that is best in medical literature.

Hämodynamische Studien. Von Dr. med. Johann Plesch. Mit 14 Abbildungen und 2 Curven im Text. Berlin: Verlag von August Hirschwald, 1909.

The studies comprising this volume of 240 pages were originally presented in the *Zeitschrift für experimentelle Pathologie und Therapie*, but their unusual interest and volume more that justify their appearance in separate form. They represent an immense amount of work in fields of great importance to the physiologist and experimental pathologist, some of it in corroboration or correction of previous investigations, but much of it in entirely new directions. The first portion of the book deals with the interesting question of the methods for determining the total amounts of hemoglobin and of blood in the body, and new procedures are described by means of which the author believes that the older figures are proven to be erroneous. The statement originally made by Welcker that the amount of blood in the human body is equal to 1/13 of the body weight has been universally accepted, yet it was founded on only three observations, and the author's very elaborate investigations show that the true value is 1/19, and that the amount of hemoglobin is 0.7 per cent. of the body weight. In the second and larger portion of the work, such matters as the minute volume, pulse volume, rapidity of the circulatory flow, and amount of energy expended by the heart are considered. The methods used in studying these questions are exceedingly ingenious and lead the author to a very extensive series of conclusions, some of which, if generally accepted, will entail more or less important revisions in this branch of physiology. Among the conclusions recorded are the following: The minute volume in the healthy, resting individual is 62 c.c. per kilogram of body weight; the pulse volume during rest is 0.86 c.c. per kilogram; the rate of flow in healthy persons is 42.4 c.c., but this is greatly exceeded in anemias, and the functional murmurs heard under these conditions depend on this cause. The time of circulation is normally 55 seconds and requires 65 heart beats. The coronary circulation receives 4.8 per cent. of the total, and the blood supply of the heart is ten times that of the rest of the body.

Tuberculosis. A Treatise by American Authors on Its Etiology, Pathology, Frequency, Semeiology, Diagnosis, Prognosis, Prevention, and Treatment. Edited by Arnold C. Klebs, M.D. With three colored plates and two hundred and forty-three illustrations in the text. New York and London: D. Appleton and Company, 1909.

The editor of this treatise confidently states in the preface that a continuous and systematized discussion of the whole subject of tuberculosis in all those phases of interest and value to the practitioner by a single author has become an impossibility. In the book edited by him every distinct phase of the immense subject is treated by a writer whose authority in the special question is widely recognized. Yet the needs of a practitioner have been kept as a guiding consideration and the editor has succeeded in avoiding most of the faults of repetition, superabundance of detail, and of theoretical discussion that often mark the joint work of many authors. William Osler has written a characteristically brief, yet lucid, historical sketch showing the gradual progress of our knowledge of the disease; his final word is a warning that sanatorium treatment will not solve the question of tuberculosis; the brunt of the battle must be borne by the practitioners at large whose skill in recognizing the disease in its earliest stages must ever stand as the first condition of successful treatment. Ravenel describes the bacteriological part of the pathology of tuberculosis, Ludwig Hektoen the anatomical part. Baldwin of Saranac has contributed the chapter on Resistance, Predisposition, and Immunity. Klebs, Coleman, and Hutchins have written on the general frequency of tuberculosis and its distribution among insane and among dark-skinned races of America. Part III, dealing with Symptomatology and Diagnosis, is the work of Charles L. Minor of Asheville. This contribution forms a most complete study of the practical side of tuberculosis. Minor has put into his study knowledge of the clinical and physical picture of tuberculosis that could have been acquired only by most extensive experience of the subject. Among objective signs the appearances in *x*-ray photographs are given special attention, so that the reader is well instructed in the interpretation of this new diagnostic method. Baldwin and Knopf have written the chapters on prophylaxis. These are not worded in general terms but give specific information with numerous illustrations of the work of prevention that is being done by the State and by individuals. Lawrason Brown writes on specific treatment with tuberculin, a detailed account of the various procedures being given. Coleman writes on home treatment with sanatorium methods, and Klebs contributes a valuable chapter on the sanatorium, its construction, rôle, and limitations in the fight against tuberculosis. Climatic treatment is considered further along and surgical tuberculosis is given a special section, again the work of several contributors. Several appendices furnish a formulary, illustrate numerous devices for the prevention of the spread of the disease, give suitable diet lists, and finally an extensive bibliography of selected works on tuberculosis. This short summary of the more important divisions of the work give an idea of its plan and extent. The execution of each separate task is vouched for by the names of contributors mentioned above. The book is distinctly a credit to the American medical profession.

Myeloische Metaplasie und fötale Blutbildung, und deren Histogenese. Von Dr. med. Heinrich Fischer. Sanatorium "Untere Waid" bei St. Gallen (Schweiz). Berlin: Julius Springer, 1909.

As the result of his embryological studies the author comes to the conclusion that the formation of the cellular elements of the blood from endothelial structures can be definitely demonstrated. The endothelial cells of the capillaries form myeloblasts, basophilic erythroblasts, and probably also megacaryocytes, and from the first two of these myelocytes and leucocytes on the one hand, and polychromatophilic and orthochromatic red cells on the other, may be developed. In regard to the controversy concerning the nature of the basophilic granules of red cells he is of the opinion that true basophilic stippling is a result of chromatin synthesis, the granules being formed from the protoplasm and not from the nucleus. This genuine basophilia must be distinguished from that due to granule formation caused by karyorrhexis, or karyolysis, and it is not a degenerative process but must be regarded as morphological evidence of mitotic cell division. The little volume forms an interesting contribution to the literature of the subject, though its value would have been very greatly increased by the addition of illustrations and a description of the staining methods employed.

Parenthood and Race Culture—An Outline of Eugenics. By Caleb Williams Saleeby, M.D., Ch.B., F.Z.R. Edin. New York: Moffat, Yard & Company, 1909.

The author of this book has already achieved a certain notoriety through his contributions to popular medicine and will probably add to the same with this new work. In it he enters the lists as an advocate of social and racial reform. The cause is certainly a most commendable one from any viewpoint. To quote Francis Galton, honorary president of the society, "Eugenics is the study of agencies under social control that may improve or impair the racial qualities of future generations either physically or mentally." Its scope and aim are therefore very broad and deserve the hearty cooperation of everyone. Physicians especially should be interested in this movement. There is great need for an appreciation by all sorts and conditions of men of the inherent possibilities for proper control of racial propagation. To quote in part: "The society exists to uphold the idea of parenthood . . . to proclaim that the racial instinct is supremely sacred and its exercise through marriage the loftiest of all privileges. Parenthood on the part of the insane, the diseased, the alcoholic must be denounced as a crime against future generations. Parenthood on the part of the worthy and fit is to be buttressed, guided, and extolled." Whether this book will advance the objects of this society is questionable.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Stated Meeting, Held October 28, 1909.

DR. C. E. TOWNSEND OF NEWBURGH IN THE CHAIR.

THE Third Annual Meeting of the First District Branch of this Society was held in Middletown, N. Y.

President's Address.—Dr. CHARLES E. TOWNSEND of Newburgh expressed his appreciation of the honor conferred upon him; the position if properly filled required the giving up of a large amount of time and labor. A subject that had given him a great deal of thought was "What was the trouble with the attendance at their meetings?" Since he had become President it had been made evident to him that there were many men throughout the southern tier of counties who were eligible and who would in every particular be good and useful members of this Society, but for some reason they did not care to join, and he was trying to find the reason for this indifference. Many of these men led lonely professional lives and yet did not take advantage of the privileges which they might enjoy by becoming members of the State Society. He wished to find out what was lacking in the State Society or whether the failure was due to the county society meetings. He believed the success of the meetings depended to a great extent upon the secretary of the County Society. Something more should be done than the mere sending out of notices as had been done for the past one hundred years. He thought that one trouble was that the meetings had been too frequent. The establishment of many small local societies throughout the State was evidence that physicians were solving the question to suit themselves much to the disadvantage of the County Medical Society. The day for the reading of the long medical paper was about over, and the need was for short papers on timely subjects. It might seem heretical, but it seemed to him that the papers should not be too technical. The average doctor at the county society meetings went sound asleep over long technical papers. He was of the opinion that changing the place of the annual meeting to Albany had made a difference to the men in the southern tier, and every effort should be made to have the annual meeting returned to New York City. Such a change would require a special act of the Legislature, but that could be accomplished if one went about it in the right way. Dr. Townsend asked the members to discuss among themselves the ways and means of making the meetings more attractive. A short scientific session followed by a luncheon which would give the men an opportunity to get acquainted with each other would be a help.

Has Our Therapeutic Knowledge Kept Pace with the Advancement of Other Branches of Medical Science?—Dr. C. W. DENNIS of Goshen presented this paper, in which he said that of all the branches of medical science there was none having a more uncertain foundation than therapeutics. Assuming a correct diagnosis in a given case there entered the factors of sanitation, bathing, feeding, nursing, the mental attitude of the patient, his surroundings, peculiarities, idiosyncrasies, opsonic power, phagocytic power, the degree and virulence of the infection, his susceptibility to medicinal influence, and finally the medicines administered. Then came the question of quality, strength, and purity of the medicinal agents selected. If the patient recovered, what means had one of determining what acted most favorably to bring this to pass? As it was impossible to determine the part that therapeutics performed in the treatment of disease, the conclusion was forced upon one that the discussion of the question whether therapeutics had progressed equally with other branches of medical science became purely a matter of speculation, and decision became an impossibility. Drug therapy was to-day the most discredited of all the branches of medicine; there probably never was a time when medical men had so little faith in the positive effects of drugs when applied to the cure of disease. There were approximately 200 separate diseases recognized and described in literature, and out of all these perhaps but one had positively and incontestibly yielded to medicine as a sole curative force—that was malaria to quinine. Exception might be taken to this statement by those who believed that mercury cured syphilis. Was serum therapy to become the agent which was to fulfill the hopes of past ages and lift the whole art of therapeutics up to an equal plane with surgery, in science and preventive medicine? While drugs might not cure as directly as our fathers believed, they did relieve, sustain, and soothe as no other agents could. This was the future field for drug therapy. After reviewing some of the former beliefs in regard to drug therapy and showing how complicated the present system of therapeutics had become, Dr. Dennis concluded that the future hope of the therapeutic art as applying to drugs lay along the following lines: (1) Dropping out of the pharmacopeia hundreds of medicines which were of doubtful utility or which were with difficulty prepared with accuracy or which duplicated each other in their range of action. (2) The State should provide a laboratory in which would be made examinations and tests of medicines to determine their strength and purity, and a law should be made prescribing a fine and punishment for offering for sale medicinal substances varying materially from a standard as defined in the United States Pharmacopœia. This was not covered by the "pure food and drug act" as he understood it. In addition skilled men should be employed to determine, physiologically when possible, the positive effects of drugs most commonly used. (3) More careful observations should be made and recorded by medical men of the effects of medicines used clinically; single remedies should be used more frequently, the ready made prescription should be largely, if not entirely, dispensed with, as it cultivated habits of carelessness and indolence. (4) Proprietary remedies should be entirely refused which did not contain the exact formula. (5) Every doctor should familiarize himself, in a measure at least, with the drugs used by other schools of medicines. No one school possessed all the knowledge of the world. (6) Careful study of each case, recognizing that nature was always making an effort to cure and not to kill, which was the direct opposite of the view which it seemed our fathers held, judging by their therapy, would lead to the adoption of those measures which removed obstacles from her pathway and strengthened her power. If drugs could not cure they could aid nature to cure; if they could not cure or aid in a cure they could relieve and thus accomplish all the prime objects of drug therapy.

Dr. ANDREW VICTOR JOVA of Newburgh said they were all interested in therapeutics, and what Dr. Dennis had stated was a straightforward and plain statement of facts. That branch of therapeutics which dealt with drug therapy had not made the advance that was made in other branches of medicine. If one went back to the seventeenth or eighteenth centuries, it would be found that therapeutics had held its own with other branches of medicine. To show that therapeutics had made some advancement, he quoted the following which he had extracted from a book of the eighteenth century on the "Treatment of Smallpox": "Let the patient lye in a little chamber close shut, and free from any wind, to the end he may the more easily breath and that the stinking vapors being the more easily discussed may the less offend him. More specially take care that no cold get into the patient's bed, for should the least cold come to him while he is in a sweat or a moist breathing, or if the patient himself by tossing or tumbling should throw off the cloaths and check his sweat, it fre-

quently happens that the pox fall in again and vanish or sinks into the skin to the great hazard of life. For which reason the patient must not be shifted till after the fourteenth day, for fear of striking in again the pox to the irrecoverable ruin of the patient. Far better is it to suffer the sheets of the patient moist with sweat to dry of themselves with the heat of the body, and for the patient for some days to bear with the stench of the sweat and the pustules coming forth, than to change his linen and be the cause of his own death. But if there is an urgent necessity for the patient to change his linen then let him have the same foul linen that he put off just before he fell sick, or that have been worn by some other sound body. For I have often observed clean and newly worked linen to be very prejudicial to sick people which I am apt to believe proceeds from the smell of the soap which the linen in some measure retains. This is certain, 'tis better not to change linen at all, but to change before the fourteenth day is a thing not to be done without extreme hazard. Nor is there any reason for any man to be afraid of any bad smell which the linen contracts from the sweat and heat and broken pustules, for that we never found it to be prejudicial to any that were ever sick of the distemper." For fifty years drug therapy had not kept pace with the advance in other branches of medicine. He believed the time would come when members of the medical profession would content themselves with the use of but a few drugs; then better knowledge of the physiological action and better results would be had. He wished there was some other way of administering drugs than by way of the alimentary canal, such as serotherapy, to which we looked forward with great expectation. Surgery had made a great advance, but not solely because of the art, but because of the discovery of antiseptics and the germ theory of disease, without which no surgeon, however skillful, could be successful in saving life.

Neurasthenia.—Dr. F. Howell Greene of Poughkeepsie read this paper, in which he stated that neurasthenia most commonly made its appearance between the ages of twenty and fifty, and consequently incapacitated its victim at that time of life when his usefulness should be greatest. Nine-tenths of neurasthenics had inherited a sensitive nervous condition from parents who were not psychically stable, or who had lowered vitality from abuse or disease. Improper training during childhood and adolescence were also predisposing causes. Both sexes were affected in about equal proportions; it was more frequent in those locations where the greatest amount of physical and mental strength was required. It was often quite difficult to learn the exact immediate exciting cause, but by careful search they would find something that depressed the mind of the victim, and from which he could not recover, even though in itself the cause might be trivial to a normal mind and known to be such by the patient. Although the pathological anatomy of the condition was not known, its manifestations were those best explained by a diminished dynamic energy and lessened recuperative power in the cerebrospinal axis, and especially in the cellular elements. The symptoms of neurasthenia were numerous and varied; they might simulate any of the graver diseases, probably through suggestion. Some of the most constant symptoms were headache, vertigo, backache, pain, gastrointestinal atony, neuromuscular weakness, insomnia, mental depression, and mental irritability, nearly always having some one subjective symptom that constantly entertained the mind of the victim. Vertigo was not as constant a symptom as headache; backache was nearly always present, usually in the small of the back, radiating upward between the shoulders and downward through the loins into the limbs. Mental depression and mental irritability were the essential factors of the disease, around which all other symptoms were grouped. These patients might have all forms of nervous irritability of the heart, as intermitting, throbbing sensation, palpitation, etc. The sexual appetite was usually diminished or lost. These patients frequently wished they were dead, but were prone to avoid doing anything to expose themselves to danger. In a few cases, however, they did commit suicide. The diagnosis of neurasthenia was usually easily made, though one might be misled by the patient giving a train of symptoms which he or she had learned from some other patient who might be suffering from some grave disease. The best differential diagnostic symptom was the minute details with which the symptoms were given in neurasthenia and which was nearly always present in the severer forms of this disease. As to prognosis, the outlook for the patient's living many years was good, though death might come when the disease took on a severe gastrointestinal type and the patient died of starvation. The most important treatment was prophylactic. The foundation for the greater number of cases was laid at home or in school. To get to the bottom of this disease they would have to commence with the parents and the home life and with the teachers in preparatory schools and colleges. Parents should avoid all demonstrations of nervousness and complaining, whether of hard luck or ill health, in the presence of their children, and should teach them to grow up strong, mentally and physically. Children should be taught that nervousness and worry from slight provocation were signs of mental weakness and cowardice, and that nervousness militated against success in life. They should be taught not to be impatient, that apparent failure at first often led to greater success in the future. Children should have plenty of fresh air and exercise; their muscles should be developed first and their minds afterwards. It was of prime importance in the schools to have conscientious, broad-minded teachers, who realized that they had undeveloped human minds to develop, minds that in a few years would be the brains of the nation if properly handled. In order to get properly trained teachers they should commence with the colleges for women, because their graduates became teachers in the normal schools, and the normal school graduates in turn taught developing children. Teachers should study the home surroundings of the child and should they find a child whose father or mother was weakened, either psychically or by disease, that child should receive special training. College instructors should remember that all of their students were members of the human race, and avoid favoritism to the popular and humiliation to the unfortunate. Laws prevented or regulated corporal punishment, but there was nothing to prevent far more dangerous treatment, unjust mental humiliation, which might forever warp or wither a mind that had every promise of being brilliant. The treatment of a case of neurasthenia was usually simple. If possible, the patient should have a change of scene, away from family and sympathizing friends, with a companion adapted to those cases. There should be proper rest, judicial exercise, tonics, and everything should be done to improve the physical condition of the patient. The diet should be supervised, elimination promoted, the nervous system sufficiently stimulated, and an abundance of sleep, not induced by drugs, should be had if possible.

Dr. Mary E. Dunning of Newburgh said that the school children in the public schools were allowed to remain indoors five hours a day, and, outside of the larger cities, were not given any physical examination to determine their fitness for close confinement. Many were not taught how to breathe, often the air itself was bad, and they were not properly nourished. They fell backward in the work year after year, and grew up to be defective. Again, they should take it upon themselves not to permit school teachers to be so overworked and underpaid.

The Application of Anthropometry to Neurological Practice.—Dr. H. L. Winters of Cornwall made this preliminary report. He stated that, in his experience, a large number of patients presenting themselves for treatment for the various forms of functional neuroses were physically inferior. The subject of physical stigmata was very old, and had, in a measure, fallen into disuse because of the extravagant claims made for it, but he had had the opportunity of following the subject in detail in the Department of Anthropology of the Pathological Institute of the New York State Hospitals for the Insane, and he had made the following measurements and observations: Heights, patient standing, to the external malleolus, to the head of the fibula, to the trochanter of the femur, to the anterior superior spine of the ilium; the patient being seated, from the seat to the acromion process of the scapulæ. Circumferences were measured over the iliac crest from central point of spinal column, at umbilicus from same point, at the ensiform cartilage from the same point, and at the insertion of the third rib and sternum from the same point. All of these measurements were made on both sides, and the amount of deformity was shown by comparison. The deformities looked for were flatfoot, severe knock-knee or bowleg, deformities of the coccyx, spinal curvature, and special deformities of the chest wall. Over one thousand examinations had been made, but only five hundred had been looked over and tabulated. Analysis of these showed that over 56 per cent. of the patients had physical deformities. Of this 56 per cent., 71 per cent. were deformities that could be corrected; 19 per cent. could be partially corrected, and 9 per cent. could not be remedied. Of those cases in which physical deformities were corrected, 83 per cent. recovered or improved without treatment. The object of the paper was merely to call attention to the value of such an anthropological examination, but a close analysis developed several striking conditions. Of the neurastrenics over 63 per cent, showed deformities, while less than 5 per cent. of hysterias were irregularly developed. Almost all of the facial neuralgic cases presented some deformity; all of the localized neuritis cases, every case of angioneurotic edema, a small percentage of migraine, and a large percentage of cephalalgias likewise presented deformities. The apparent inference was that some of the so-called functional neuroses were more dependent upon the maintenance of general physical balance than others. This difference was strikingly shown to exist between neurasthenia and hysteria, and the fact that the one case of hysteria which showed deformity was not benefited when the deformity was corrected bore out the idea suggested by the figures, that hysteria probably had a more definite pathological basis than neurasthenia. Further similar comparisons were possible. A comparison of results obtained by deformity correction, without treatment, and the usual treatment in cases without deformity showed over 60 per cent. of cures by the former method and little more than 31 per cent. by the latter. The results showed the necessity for a system of measurements for use in routine practice.

Anesthesia and Anesthetics.—Dr. Robert Cordner of Middletown, in discussing this subject from a practical standpoint, protested against the indiscriminate habit of touching the eyeball with the finger while the patient was under the influence of an anesthetic. Contusions of the cornea were liable to occur, with their accompanying complications. The majority of surgeons to-day favored ether because it did not require so much care in administration. It was a good rule in the administration of either of these drugs to allow the patient plenty of fresh air and to use as little of the anesthetic as would accomplish the object of the operation. The special methods of anesthesia for operations about the head, nose, and throat deserved more attention. He referred to rectal anesthesia and to an ether vaporizer operated by a foot pump and conducting the ether vapor by means of a rubber tube to an ether tube located in one of the jaws of the specially constructed mouth gag. It was easier to prevent collapse of a patient than to treat such collapse, and to this end supportive measures during certain operations should be resorted to, heat should be applied about the cardiac region and extremities, hot saline with whisky as rectal enemata, and hypodermics should be given. Nitrous oxide gas preceding ether obviated to a large extent the disagreeable features of ether anesthesia alone. This method should be more generally employed. Whenever possible, the patient should be given the benefit of previous preparation for the anesthetic. The urine, the heart, and the pulse should be examined before giving an anesthetic. The anesthetist should be provided with a mouth gag, tongue forceps, sponge holders, and small squares of gauze previously moistened with water. Mathieu's tongue holding forceps was preferable to the needle forceps. There was a point which needed clearing up, and that was whether morphine safeguarded the respiratory and circulatory systems during anesthesia or not. This was a problem needing more research work. The danger from anesthetics depended largely upon the condition of the patient at the time of operation. When grave symptoms arose it was well, in addition to the usual restoratives, to tilt the table so that gravity would assist the flow of the blood to the head. Dr. Cordner referred briefly to the various local anesthetics.

Some Further Considerations on the Employment of Solid Carbon Dioxide as a Therapeutic Agent.—Dr. William S. Gottheil of New York read this paper. He stated that carbon dioxide was being increasingly used, and with gratifying success, in a variety of obstinate dermatoses and deformities. Everything depended, however, in drawing it from the gas tanks in suitable form and in a proper degree of coldness and hardness. The technique was simple, and required nothing more than a towel and some bandages. The author rejected as needless and inappropriate the various forms of apparatus that had been proposed in order to facilitate the process, and gave in detail the method which he employed. The severity of the congelation, frequency of application, etc., varied with the results to be attained. Every grade of effect, from an amount of destruction so slight as to leave absolutely no scar, to complete destruction of the entire integument could be obtained at will. When scar tissue was produced the resultant cicatrices were smooth, soft, and non-contractile to a degree unattainable by any other method. The pain of the application was very moderate indeed, hardly more than that of freezing by ethyl chloride. Carbon dioxide was essentially an anesthetic cauterant, and could be used in infants and old people without hesitation. Over nerves, and in the immediate neighborhood of structures like the eye certain protective measures had to be employed. The remedy had passed the experimental stage, and was in almost daily use by the author and his assistants both in private and in public practice. It was employed with most satisfactory results in nevi and angiomata, in pigmentary and hairy congenital growths, in xanthomata of the lids and other benign tumors, in papillomata, in senile warts, in rodent ulcer and fungating epitheliomata, in the precancerous keratosis, in malignant degeneration of the skin following radiodermatitis, in lupus erythematosus; in fact, everywhere on the skin where a non-painful, effective, extremely manageable and cosmetically desirable destructive agent was required. The field of its usefulness was being constantly extended; but in the above mentioned affections it had been thoroughly tested and its value ascertained. It was especially useful in the extensive obstinate cases in which one was

formerly almost helpless. The author did not hesitate to say that in the domain of dermal therapeutics its field was larger, its results more certain, and its value greater than the *x*-ray.

The Treatment of Pelvic Infection with Special Reference to Bacterial Vaccines.—Dr. Frank R. Oastler of New York read this paper. He said that it was not very long ago that ovaries, tubes, and uteri were removed as proper treatment for conditions which to-day were successfully handled by less radical methods of procedure. A more accurate knowledge of the many disagreeable features of the artificial menopause had possibly led to this result and now, with the introduction of antitoxins and bacterial vaccines, there was a possibility that radical methods might be further curtailed. He said it was not the purpose of his paper to go into the minute details of the common treatment of pelvic infections, but simply to dwell at some length upon certain features in the treatment which seemed important and new. They all appreciated the fact that the streptococcus, the staphylococcus, the gonococcus, and the *Bacillus coli* were the common parasites that invaded the pelvis. They understood that infection might travel by way of the broad ligaments to the tubes, ovaries, and peritoneum on the one hand, and by way of the uterus and tubes to the ovaries and peritoneum on the other. Secondary infection might also develop from inflammations of other organs in the pelvis or neighborhood, and infection by direct transmigration of the colon bacillus from the intestinal canal was much more common than was formerly supposed. It had furthermore came to his knowledge of late that pelvic infection might be brought about by the pneumococcus with the consequent localized pelvic peritonitis and tubo-ovarian involvement. He was able to report six such cases. With the invasion of the pelvis by these various pyogenic bacteria, examination of some two hundred cases led to the conclusion that the exact rôle played by these organisms had not been fully determined. In fifteen cases of the more virulent forms of puerperal septicemia treated, the *Streptococcus aureus* was found alone in five cases, mixed staphylococcus and *Bacillus coli* in six cases, pure *Bacillus coli* in one and *Streptococcus pyogenes* in three. In the determination of the treatment of the various conditions resulting from the introduction of these organisms into the pelvis, they must first remember that the pelvic organs should be considered separately, and secondly that they had to deal with (*a*) simple inflammation or (*b*) a suppurative process resulting in disease of the uterus and tubes, or more rarely the ovaries. The pelvic organs naturally by their location were so situated in the abdomen that they could be more readily walled off by protecting adhesions than other organs in the abdomen, and, generally speaking, the virulence of the invading germs appeared to be of a milder character than those attacking other organs of the peritoneal cavity. This had led to the rule among gynecologists that it was the better policy to wait for the acute inflammatory process to become subacute or chronic before attacking them surgically, with the conviction that, when the disease was attacked, the process would have sufficiently subsided to have become so localized that it could be the more easily attended to and without the destruction of as many organs. And, too, what was of much more importance, the resulting pathological condition of suppurative inflammation, though present and active, was most always found to be germ free, thus allowing the spilling of pus in the pelvic cavity with a certain degree of impunity. That this general method of procedure was rational and advisable in most of the severe inflammatory conditions of the pelvis was beyond cavil, yet there were certain exceptions to this ruling to which attention was called. Simple inflammatory conditions generally responded to rest, the ice cap, free catharsis and, later, the douche and tampon. Curettage was necessary when the process was associated with endometritis, or retained membranes. Special treatment was required, depending upon the etiology of the particular inflammation. The invasion of the gonococcus into the pelvis through the uterus into the tubes, finally reaching the peritoneum, was very often of a violent nature, resulting in localized suppurative inflammation of tubes, or tubes and ovaries, with pelvic exudate, even, rarely, resulting in general peritonitis. A condition of inflammation often overlooked and a cause of sterility was in that class of cases where there had been continuous bleeding from the uterus for a long time as a result either of incomplete abortion or of severe chronic hypertrophic endometritis. For the past two years Dr. Oastler had been at work endeavoring to classify the variety of pathological conditions for which the bacterial vaccines were of value. Up to the present it would seem that the greatest good could be accomplished in the treatment of subacute or chronic pyemia or septicemia resulting from pelvic infection. The acute violent cases of puerperal sepsis did not respond to the bacterial vaccines. Knowing the tendency of pelvic infection to localize itself and gradually subside in the less severe cases, it was hard to determine how much good they did with the vaccines; but in the severe cases the value of the vaccines could often be estimated. Vaccines did not seem to cause infection, but simply to aid in stimulating increased resistance and so combating sepsis, often turning the tide in favor of the patient. They were indicated especially in conditions of poor resistance. The dosage was, as yet, in the stage of experimentation. Results had been more satisfactory with the *Staphylococcus aureus* and the *Bacillus coli*, and less with the streptococcus. Attention was called to the great frequency with which the *Bacillus coli* was found in pelvic inflammations. The treatment of pure gonococcus infections with vaccines had been very disappointing, especially in the treatment of gonorrheal urethritis.

Lactic Acid and Lactic Acid Bacilli.—Dr. W. S. Gleason of Newburgh presented this paper, in which he referred to the work of Massol, Metchnikoff, and Cohendy in relation to the Bulgarian bacillus. He said that the average practitioner should use judgment in selecting the best product to carry out successfully the application of this means of combating disease. At present one was able to obtain the lactic acid bacilli in one of the following forms: Ready soured milk, liquid cultures in bottles for internal administration, tubes of liquid ferment for souring milk, and finally a variety of dry ferments in the form of tablets. In giving the dry tablets it was necessary to follow the dose with sweetened water or malt, as a saccharine solution favored the growth of lactic acid bacilli. The ordinary lactic acid bacteria, as of buttermilk, were incapable of resisting the secretions of the digestive tract, and spontaneously soured milk was not the same as Bulgarian soured milk. The Bulgarian lactic acid bacilli caused the formation of lactic acid in the intestinal tract, which produced an antiseptic action checking intestinal putrefaction, a tropical action on diseased conditions of the intestine and also a constitutional effect due to the absorption of lactic acid. In the treatment of diarrheal diseases of infants and young children the reports, as a whole, were favorable. Cultures of lactic acid bacilli had been used successfully in sinus and nasal conditions. In atrophic rhinitis 88 per cent. showed decided improvement. A large proportion of frontal sinus cases were helped. The treatment of ethmoiditis and antrum trouble with the lactic acid bacilli had proved most satisfactory, but the best results were achieved in otitis media where the otitis complicated diseases of the nose and accessory cavities. Dr. Gleason reported the case of a previously healthy young man who was affected with subacute diarrhea of prolonged and un-

usual intensity. Diet, medication, and rest gave only temporary relief. Illumination of the colon disclosed a congested mucosa punctuated with minute ulcerations. Fecal examination showed a large flora of colon bacilli with streptococci and staphylococci. All medication was stopped excepting nitrate of silver irrigations; these were also gradually withdrawn, and Metchnikoff's lactic bacillary tablets in a sweetened media in four hour doses were administered. This plan was carried out carefully for several weeks in diminishing doses, the stools becoming less and less frequent until they became normal. There was a place for the lactic acid bacilli in combating the toxemias due to saprophytes or the bacteria of putrefaction in typhoid fever. Dr. Gleason had carried out this method in eight cases of typhoid fever, beginning the treatment at the middle of the second week so as to prop up the weakened barriers of the system against the increased autointoxication. Under this treatment the cases under observation showed a lowered temperature curve, the abdominal tenderness gradually disappeared, and the patients were manifestly more comfortable and convalescence was unusually rapid. These cases were of very severe type and were treated in other respects in the routine manner. The results seemed to favor a further trial of the lactic acid bacilli for the purpose of fortifying the system in typhoid until the vaccine treatment was on a better basis. The lactic acid bacillus was inert against the typhoid germ, but it would evidently destroy the putrefactive flora of the intestines.

Acute Diffuse Suppurative Peritonitis.—Dr. James E. Sadlier of Poughkeepsie read this paper.

Election of Officers.—*President,* Dr. Theodore D. Mills of Middletown; *Vice-President,* Dr. W. Stanton Gleason of Newburgh; *Secretary,* Dr. Charles Ellery Dennison of New York; *Treasurer,* Dr. James E. Sadlier of Poughkeepsie. Next place of meeting, Newburgh.

The Pathological Society of Philadelphia.

At a stated meeting held October 28 Dr. John M. Swan exhibited a specimen of "metastatic cancer of the lung from cancer of the breast." No operation had been performed and a general carcinosis developed. Dr. Swan exhibited also a specimen of "metastatic cancer of the liver from primary cancer of the rectum." The liver was studded with innumerable secondary masses, increasing its size to large dimensions. Dr. Alfred Gordon exhibited a specimen of "diplomyelia." The specimen was obtained from the body of a young man who lived to the age of fifteen years and for a long time presented only mental deficiency without motor phenomena. Toward the close of life convulsions set in and these increased in frequency until status epilepticus developed and terminated fatally. On post-mortem examination, in addition to porencephaly, a portion of the cord between the lower thoracic and upper lumbar divisions was found divisible in two parts, each of which represented an individual cord with areas of gray matter and tracts of nerve fibers united at their contiguous margins and enveloped in a single covering of dura mater. Somewhat higher up the cord contained a cavity of considerable proportions, involving the anterior horns. The cerebral dura contained deposits of bone adjacent to the longitudinal sinus. Dr. Warfield T. Longcope exhibited a specimen of "aneurysm of the vertebral artery and of the celiac axis." The patient was a man who had suffered from attacks of severe headache for a number of years. The last attack had lasted six or seven days before admission to hospital and had been attended with loss of consciousness and a fall. In addition there was rigidity of the neck and elevation of temperature, but no leucocytosis. Lumbar puncture was performed six times and on each occasion bloody fluid was obtained. On post-mortem examination the subdural space at the base of the skull was found distended with blood, from rupture of a vertebral artery, and the surface of the cord also was enveloped in blood. In addition, the celiac axis was found to be the seat of an aneurysm. Both formations were found to be in the nature of dissecting aneurysms, the blood finding its way between the layers of the vessel wall through a laceration in the intima. Dr. George P. Muller exhibited a specimen of "angioma of the liver." The specimen was obtained from the body of a woman presenting symptoms of suppurative appendicitis, with abscess formation, and also of cholelithiasis. The first incision was made over the gall-bladder, and the liver was found to be the seat of a new growth that bled profusely on incision and accordingly was not removed. Subsequently the appendiceal abscess was incised and closed. Septic infection, however, developed and the patient died. The formation in the liver was found to be a cavernous angioma of considerable size. Dr. Aller G. Ellis presented a specimen of "tuberculous ulceration of the stomach," and he referred to a specimen of similar kind previously exhibited. Dr. Karl Schaffle presented specimens of "multiple renal calculi." The pelvis of the kidney was converted into a polycystic cavity and its calicies were filled with numerous calculi, some of which were molded to the shape of the spaces in which they lay. Dr. George Draper presented a communication entitled "Multiple Calculi in the Intrahepatic Bile Ducts with General Infection with Bacillus Coli," and he demonstrated the specimen. The patient had presented repeated chills and feverishness at irregular periods, with a muddy rather than an icteric hue, and a moderate leucocytosis. Cultures from the blood revealed *Bacillus coli communis* in pure growth. After death the gall-bladder contained a single calculus, while a number of stones were distributed throughout the dilated biliary system. The ducts were patulous and bile flowed readily through all of them. Dr. John H. Musser presented a communication entitled "Self-Defense Against Disease, a Chapter in Pathologic Physiology." He cited the various defensive mechanisms that exist within the body to protect it against the invasion of pathogenic microorganisms and other forms of irritation that threaten harm to the organism and also those concerned in the conflict with established disease, as well as with the process of recovery. The physician has to do with the individual and with his reactions to morbid processes, and the recognition of this fact will prove a great aid in the intelligent application of therapeutic measures. He must ever be sure that at least he does no harm even if he does no good.

Philadelphia Pediatric Society.

At a stated meeting held October 12 Dr. Carson reported "A Case of Pica in a Mentally Defective Child," and he exhibited the patient, a child a little more than two and a half years old, that in the sequence of an acute illness, followed by convulsions, exhibited mental deficiency and a tendency to eat unusual articles, to gnaw wood, to chew and swallow substances like oilcloth, bedticking, and strings. Dr. Charles A. Fife read "A Report of Three Cases of Cerebral Spastic Paralysis in One Family," and he exhibited two of the patients. One of the latter was three months old and the other sixteen months old. Both presented spasticity, with exaggerated reflexes and athetoid movements, while another child that had died was said to have exhibited similar phenomena.

There were two other healthy children in the family. The labors had been easy, but not precipitate, and there was no history of traumatism or of infectious disease on the part of the mother during pregnancy. The mother, however, had exhibited during pregnancy profound mental depression, and this, it was thought, might have an influence in the development of the affection in the children. Dr. J. Claxton-Gittings read "A Further Report on a Case of Leukemia," previously exhibited. The patient had presented an enlarged spleen and liver, and a moderate increase in the number of leucocytes, with a marked preponderance in the number of lymphocytes. The patient had meanwhile died, but an autopsy could not be secured. Dr. Howard T. Karsner read a paper entitled "Mixed Leukemia." He dealt especially with the splenomedullary type of the disease, as it is observed in early life, and of which he reported a case, and also seven other cases collected from the literature. He contended that the affection had its own definite pathology and histology, by means of which it could be recognized. Dr. John H. Jopson read a paper entitled "Congenital Imperforate Rectum; Report of Two Cases." In one of these the entire colon was represented by a solid strand. An artificial anus was established in the left iliac region, but the patient did not survive. The meconium was thickly inspissated, and its removal was attended with great difficulty. In the second case the operative relief was successful, but the patient was surrounded by such unfavorable conditions that it died from malnutrition. Dr. Robert R. Walker read, by invitation, the "Report of a Case of Pelvic Abscess Due to Ruptured Empyema." The patient was a child presenting symptoms of rachitis, with an enlarged spleen and a contiguous mass, signs of peritonitis, and a moderate leucocytosis. On post-mortem examination a large abscess was found occupying the abdominal cavity and the pelvis, and communicating through an opening in the diaphragm with an empyema in the left pleural cavity.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Diseases of the Skin. By James Nevins Hyde, A.M., M.D. 8vo; cloth; 1126 pages: illustrated. Lea & Febiger, New York.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of November 20, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	528	181
Diphtheria	353	32
Measles	301	8
Scarlet Fever	232	14
Smallpox	—	—
Varicella	145	—
Typhoid Fever	77	16
Whooping Cough	57	3
Cerebrospinal Meningitis	4	4
Malarial Fever	—	—
Totals	1,697	258

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended November 19, 1909:

		CASES.	DEATHS

THE FUNDAMENTAL FUNCTIONS OF THE MUSCLE-CELLS OF THE CARDIO-VASCULAR SYSTEM, WITH THE SUGGESTION OF A CLASSIFICATION OF ARTERIAL DISORDERS.*

BY LOUIS FAUGÈRES BISHOP, A.M., M.D.,

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY; PHYSICIAN TO THE LINCOLN HOSPITAL.

THE fundamental object of the art of medicine is the cure of disease. As physicians, we have no right to devote our time to any work that does not ultimately lead to this end. We can for a time cease to be physicians and become pure scientists, devoted to the discovery of scientific truth, and in doing so we become participants in a great and glorious work, but at the same time we cease to be physicians. The physician, as such, is devoted solely to the application of medical knowledge and the cure of disease as a vocation. He looks doubtfully upon those who indulge a tendency to plunge into the realm of theory and speculation.

So there are two great masses of medical knowledge, the one representing the great volume of records, facts, theories, and investigations that are carried on by scientists in connection with the subject of medicine. These are recorded in the minds of these scientific men and in the hundreds of thousands of volumes in medical libraries.

The other mass of medical knowledge represents the actual application of accepted principles to the alleviation of disease and the prolongation of life.

From time to time there is an opportunity to transfer knowledge from the realm of investigation to the realm of practical medicine, and it is to make a beginning in this direction, with regard to the subject of the paper, that I have undertaken to open the discussion this evening. To me this knowledge has converted the treatment of cardio-vascular disease from a matter of hopeless drudgery to a thoroughly satisfactory and delightful calling. The principles are so simple that they can be defined in a few words, viz., a due regard to the facts of evolution and physiology, without an undue regard to the appearance presented by pathological anatomy.

And here I would like to express the belief that the functions of the muscle-cells of the blood-vessels possess the same functions, modified, of course, by circumstances, that are found in the muscle-cells of the heart, and that in forming the mental picture of a case of circulatory disease, we must endow all the muscle-cells of the whole cardiovascular system with the functions of the heart muscle-cells.

We cannot proceed without giving credit to [illegible]kell, Mackenzie, Russell, and other English w[illegible] who have done so much to elucidate this su[illegible]. In the second chapter of Mackenzie's book on the heart we find the best brief enumeration of the fundamental functions of the heart muscle-cells.

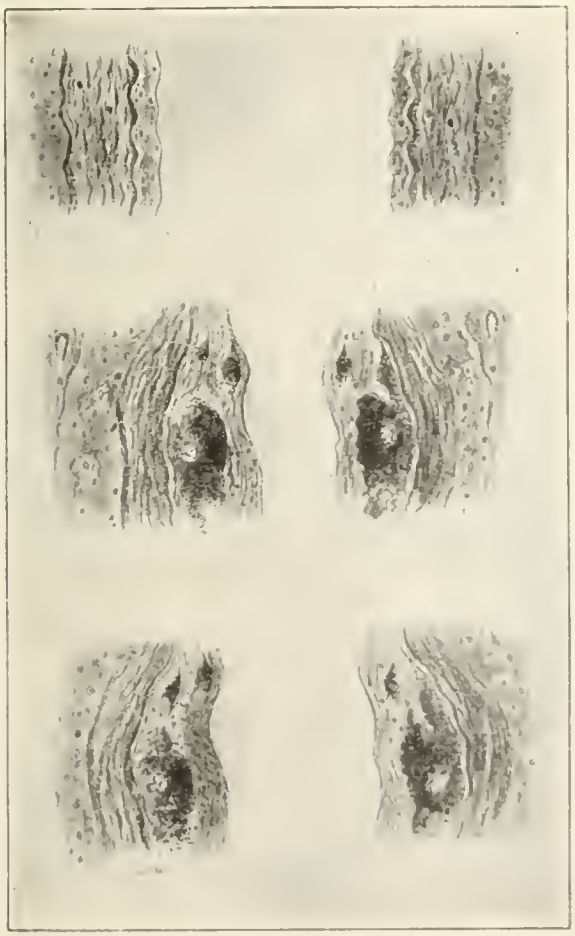

FIG. 1.—Hypertonia vasorum with atheroma; upper line, section of a normal artery; middle, atheromatous artery contracted; lower, atheromatous artery relieved of hypertonicity.

This I have adapted to the use of this paper. He says in part:

"From the consideration of the physiology of the cell, it may be said that every function possessed by a cell in the fully developed state exists partially developed in the primitive state. However specialized the function may be, nervous, muscular, secretory, these functions can be referred back to some property possessed by the primitive cell. The cells which constitute the primitive structure of the body all start equally endowed, and it is by a gradual

*Read before the Medical Association of the Greater City of New York, October 18, 1909. The illustrations accompanying this paper are taken, through the courtesy of E. B. Treat & Co., from the forthcoming third edition of the author's work on "Heart Disease, Blood Pressure, and the Nauheim-Schott Treatment."

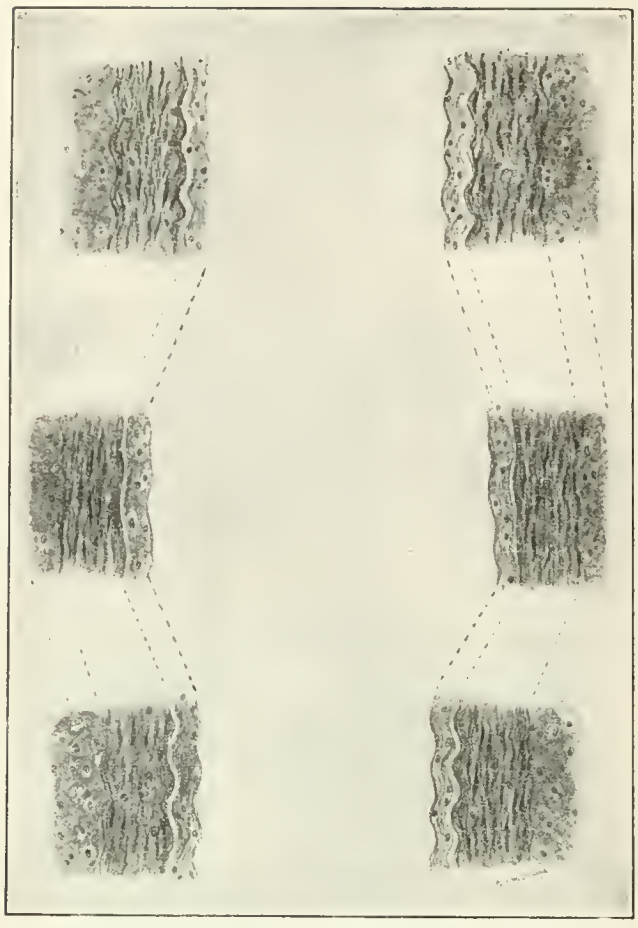

Fig. 2.—Hypotonia vasorum; upper line, section of normal artery; middle, section of dilated artery; lower, section of artery after restoration of tone.

process of specialization that each takes on its peculiar function, while as it acquires a high degree of specialization it gradually loses those functions it no longer exercises. The functions possessed by the primitive cells can be therefore deduced, not only from the results of direct observation, but from the specialized functions of the more differentiated tissues, even if these functions be so highly developed that they bear little resemblance to those found in the primitive cell. For instance, the excitability of the cell may become so specialized that it is only responsive to certain stimuli, such as, pain, light, sound, while all its other functions are apparently lost. If one looks at the functions of nerve and muscle-cells in the full developed state, it seems at first sight difficult to realize that they had originally identical functions. The primitive cells from which the heart developed had all the same characteristics, yet in their final evolution they present widely divergent characteristics, both in appearance and in function. That some such modification does occur must be inferred when we witness the change in function that takes place in the evolution of the heart from the primitive cardiac tube."

Mackenzie suggests this as a working hypothesis: "In the evolution of the heart-muscle fibers certain functions of the primitive cells were retained, some of these being more developed than others according to the duties the fibers had to perform, so that while they have come to resemble muscle-fibers, they nevertheless retain in a varying degree some functions which are highly specialized in the nerve cell. The special functions which Gaskell has demonstrated are five in number, viz.:

1. The power of producing a stimulus which can excite the heart to contract—stimulus production.

2. The power of being able to receive a stimulus —excitability.

3. The power of conveying a stimulus from fiber to fiber—conductivity.

4. The power of contracting when stimulated—contractility.

5. The power to retain a certain amount of contraction even when the active movement has ceased —tonicity.

Stimulus Production.—From this point of view it is assumed that muscle-fibers of the heart, if supplied with appropriate nutriment, possess a power to secrete internally a material which is capable of stimulating the fiber to contract. This material is being continually secreted, and during a pause in the heart's contraction, accumulates in the heart cell. When sufficient has been stored to excite the heart to contract, the whole store is used up in stimulating the muscle-cell. Immediately after the contraction the store begins to accumulate until sufficient has been produced to excite the heart to further contraction. This function, being continuous in its action, cannot control the rhythm of the heart, but by its cooperation with the other functions a rhythmical character is given to the accumulation and destruction of this material.

Excitability.—The heart muscle depends for its contraction upon its power of receiving a stimulus, that is, upon its excitability. Immediately after the heart has been stimulated to contract, excitability has disappeared, and the fibers are what is called in the refractory stage. The excitability begins at once to be restored, and increases very rapidly during

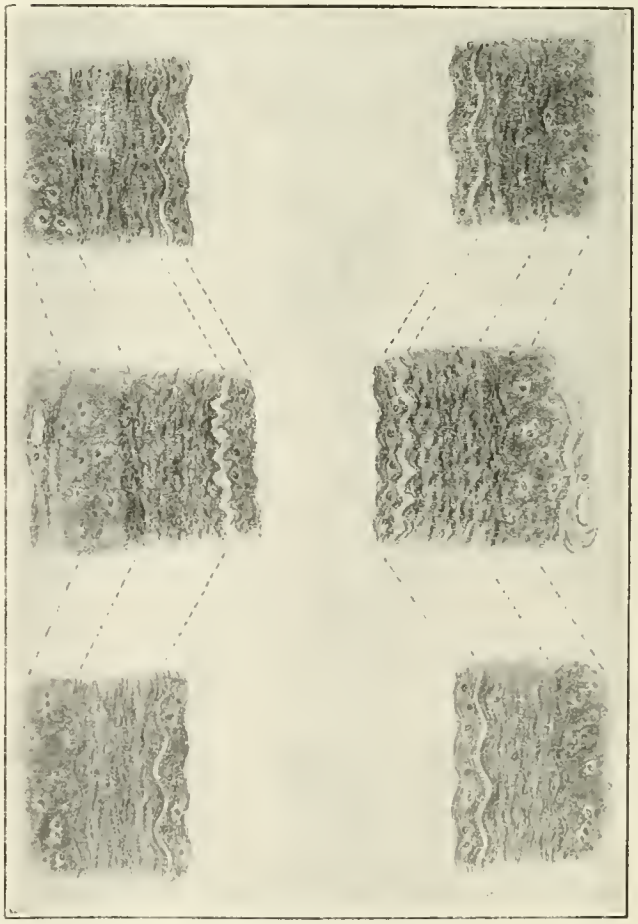

Fig. 3.—Hypertonia vasorum; upper line, section of normal artery; middle, section of contracted artery; lower, section of artery restored to its natural partial contraction.

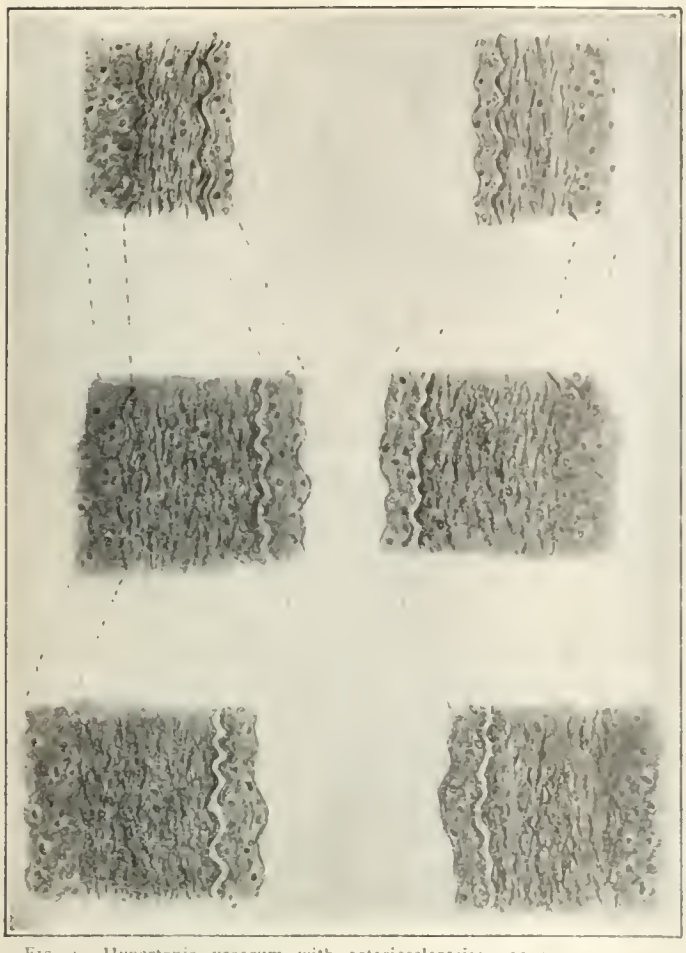

Fig. 4.—Hypertonia vasorum with arteriosclerosis: upper line, section of normal artery; middle, arteriosclerotic artery, contracted; lower, arteriosclerotic artery relieved of hypertonicity.

diastole. This is demonstrated by the heart being susceptible to weaker stimuli the longer the time since previous contraction. So long as the heart is capable of contracting, the rate of the heart depends upon the functions of stimulus production and excitability, and when the conditions are normal the equal action of both functions—the stimulus material being renewed at a uniform rate, and the restoration of the excitability taking place at a uniform rate—a regular rhythm of the heart's action results. Under normal circumstances, therefore, the heart's rate and rhythm are dependent upon the integrity of these two functions.

Conductivity.—In a mass of primitive cells the individual cell has a power of passing the stimulus on to neighboring cells. This function of conductivity is possessed by the heart muscle-fibers, for the stimulus is passed on from cell to cell from the point where it originated. The possession of this function by the muscle-fibers of the heart gives them a character which is typical of certain forms of nerve-fibers, but in the heart this is not so highly developed as in the specialized nerve-fibers, the conduction of the stimulus not being so rapid in all cases, and much more easily exhausted. Like every other function of the heart, it is entirely abolished after it has been exercised, and it returns gradually. The rate an impulse travels also varies in different fibers of the heart. Some fibers such as the more recently developed contractile fibers of the auricle and ventricle, conduct the stimulus with much greater rapidity than the fibers which convey the stimulus from the auricle to the ventricle.

Contractility.—The power of contraction is the most evident of all the functions of the heart. By the coordinated contraction of the fibers of the different portions of the heart, the circulation is maintained. After a contraction, this function is completely exhausted, and the power returns very gradually. Within certain limits, the strength of the contraction depends upon the length of the period of rest preceding the contraction, the function gathering strength during quiescence.

Tonicity.—The functions of the heart muscle do not differ, except in degree, from those of other muscular structures, and as tone is a very characteristic property of muscular tissue, it is certain that the heart muscle will possess it, and it is shown by the fibers not relaxing to their full length during diastole. On account of the rapid action of the heart it is not easy to demonstrate this function. Gaskell has shown that the degree of relaxation depends upon the amount of tone present, and that certain drugs increase or diminish the amount of relaxation. Thus, veratrine and digitalis prevent the relaxation of the heart muscle in the frog so that the heart remains longer in the condition of complete contraction, the relaxation gradually becoming less and less, till finally it is almost impossible to recognize individual beats. On the other hand, solutions of lactic acid and muscarine produce the op-

posite effect, the heart becoming more and more relaxed, the contraction diminishing in size till the heart stands still in diastolic relaxation. Just as certain portions of the musculature have certain functions more highly developed, it would not be unreasonable, as Gaskell says, to expect that different parts of the heart should vary in their tonicity. That this expectation is justified will be manifest when all the symptoms of heart failure are considered, and it is only on recognizing that the heart possesses this very important function that we can understand some of the most significant features of heart failure.

Coordination of Functions.—When the complicated action of the heart is considered, it will be readily recognized that though all the fibers may be endowed with these functions a further specialization is necessary for the coordinated movement of the different parts of the heart. If all the fibers were equally endowed, then all would contract simultaneously. As it is, certain fibers at the venous end have the functions of stimulation and excitability more highly developed than others, so that after a brief period of rest the contraction starts in them. The stimulus proceeds then to adjoining fibers in such a manner that the process of stimulation and contraction sweeps over the whole heart, with the result that the different chambers and different parts of each chamber contract in that order and degree necessary to the efficient carrying on of the circulation.

Characteristics of the Functions of the Heart Muscle-Fibers.—While the heart may be said to carry on its work in consequence of its possession of these functions, there are other important features in each which have a practical bearing on the symptoms of disease and the principles of treatment. The integrity of these functions depends upon the supply of suitable nutriment and sufficient time of inactivity to recover after their exercise. When a contraction takes place, all the functions have been exercised to the full extent of the power possessed by the fibers at the moment of stimulation. No heart cell exhausts only a portion of its functions; when stimulated it uses all the energy which it possesses (all or nothing). For a brief period after their exercise, the functions cease to exist; recovery, however, begins at once during the period of rest, and each function in time regains its strength, so that, within certain limits, the longer the delay the more complete the recovery, and the more efficient is the subsequent action. It is by fully appreciating the effect of rest and proper nourishment that we gain the best conception of the principle that should underlie our treatment of heart failure. While all the functions when exercised use all the force they possess, they nevertheless manifest a quality whereby they can respond under certain circumstances, with a greater activity. Thus the rate may be suddenly increased and at the same time the stimulus passed on from the auricle to the ventricle with increased rapidity, and the contraction be executed the quicker. These changes are to a great extent under the control of the

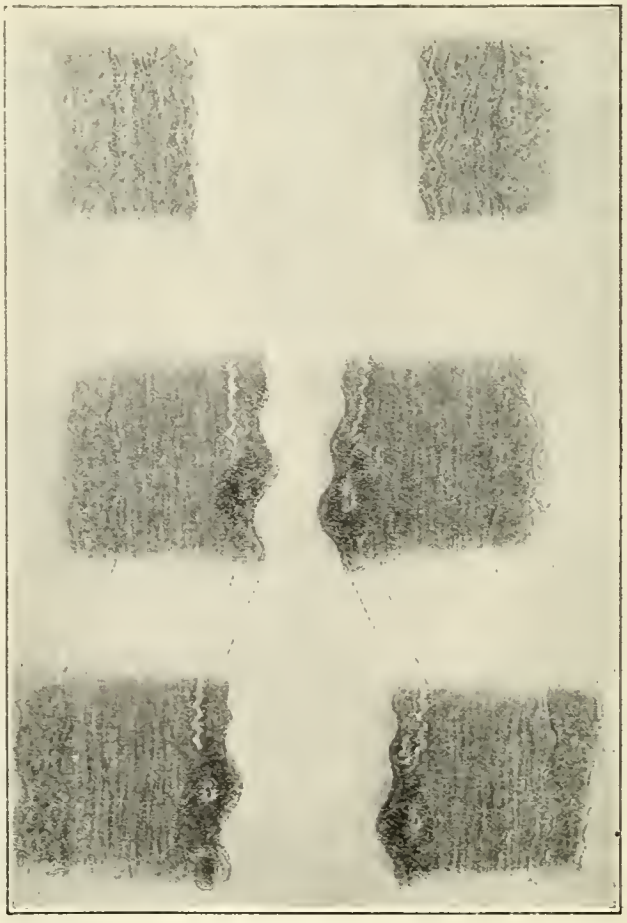

Fig. 7.—Hypertonia vasorum with hypertrophy of the media, sclerosis, and atheroma; upper line, section of normal artery; middle, artery with hypertrophy of the media, sclerosis, and atheroma, contracted; lower, the same relieved of hypertonicity.

nervous system, but they imply a quality possessed by all these functions which is of vital importance in study of the failure of the heart.

When one reflects that all the fibers of the heart are not equally endowed with the same functions, and that all the functions may not always be exposed to an equal strain, it is but reasonable to conclude that conditions may arise where they are unequally affected. As a matter of fact, that is what commonly happens, and it is an interesting and important question to consider in each case of heart failure what functions are specially at fault."

Passing from the functions of the heart muscle to those of the blood-vessels, we find that the function of the cells of the median or muscular coat of the blood-vessels which is of the greatest present importance, is tonicity, although I venture to believe that after a while we will eventually be able to understand the relation between arterial disease and the other functions, such as excitability, conductivity, and contractility.

It is certainly true that the muscle-cells of the blood-vessels are just as capable of acting independently of the nervous system as are those of the heart. So we shall probably have to add the property of stimulus production. At present, however, I have found in clinical work, the most useful classification of arteriosclerosis, using the term in the broadest sense, to be founded upon tonicity of the median coat.

The preceding diagrams attempt to show my own mental picture of the condition of the blood-vessels before and after successful treatment.

The first diagram represents hypertonus vasorum with atheroma, showing the effect of hypertonicity and the condition of the artery when this is relieved. Atheroma occurs almost as a certain event in the history of nutrition, as life advances. It may exist for years without any effect on the individual, as the diagram suggests, but if hypertonic contraction complicates it, serious results follow.

The second represents the condition of the arteries found in neurasthenia and from depressing diseases, which may be of toxic origin, and consists of a relaxation of the median coats of the blood-vessels. I have labeled it hypotonia vasorum. The diagram shows a section of the normal vessels, a section of the vessel when dilated, and a section of the vessel when restored. This condition must be familiar to all clinicians, and represents a temporary loss of tonicity of the blood-vessels. In shock of sudden onset, I believe this is always primarily present, but that if the heart is profoundly affected it is soon replaced by a compensatory hypertonus that gives the high blood pressure reading that has led to so much confusion.

The third diagram shows a simple hypertonicity of the muscle-cells of the median coat, the condition just mentioned as coming from shock. It represents physiological reflex to create the blood pressure that is required in the body. It is also supposed to be caused by direct action of the toxins of the blood-vessels, but this seems to us doubtful. It seems certainly to be caused by conditions of the nervous system. In this class of cases, the vessel is healthy in structure though disordered in function.

The fourth diagram represents hypertonicity of the muscle-cells of the median coat in simple sclerosis. This is a very important division because the diagram illustrates the effect of relaxation of the median coat on the caliber of the artery which may result from appropriate treatment.

The fifth diagram shows hypertonus with hypertrophy of the media. This condition is accompanied by hypertrophy of the heart and is a frequent association of those cases that are gone on to cardiac dilatation. It is the most serious lesion of the blood-vessels, and is ordinarily accompanied by an increase of the connective tissue and other lesions, as is shown in subsequent diagrams.

The sixth diagram shows hypertrophy of the media, with sclerosis; (*a*) a normal artery for comparison; (*b*) the artery contracted; (*c*) the artery with its hypertonicity relieved.

The seventh shows the same relative conditions with hypertrophy of the media, sclerosis, and atheroma.

It has seemed to me in clinical work that cases of arteriosclerosis, using the term in the broad sense covering all forms of arterial disease and degeneration, could be divided into groups corresponding to the changes shown in these diagrams, and that in all of them the important element to be considered is the condition of the fundamental functions of the muscle-cells, particularly the function of tonicity.

I am sure it is very easy to pick out among people with poor circulation from nervous and exhausting conditions, plenty who are distinctly suffering from loss of tone of the blood-vessels. It is likewise easy in clinical work to detect hypertonicity of the arteries. The small, cord-like, radial pulse, the high blood-pressure reading, often under conditions of heart failure, and the toxic appearance, all make hypertonicity easy to diagnose.

The onset of sclerosis in a case of arterial disease is not always so easy to prove, still quite early in the disease the pulse, the tortuous and visible temple arteries, the thickening of the artery at the wrist (when it is not contracted and the tension is not high), the symptoms of impaired circulation in the viscera, and the tendency to albuminuria, make at least a fairly clear diagnosis.

Atheroma of the arteries is easily detected in the arteries that can be palpated, by the existence of nodular irregularities; but barring the danger of accident from rupture, this lesion is not so important as sclerosis.

Hypertrophy of the media is the most important lesion in many cases, and it is to be suspected where there has been long-continued high pressure with hypertrophy of the heart. When it has developed, it is often extremely difficult to control the blood pressure. It is to be detected by a thickening of the artery which is more marked than in sclerosis. It is often a nice question to decide how much a thickened artery is due to fibrous tissue and how much to a contracted, hypertrophied median coat.

While cases are not infrequent in which these lesions, viz., hypotonicity, hypertonicity (both purely functional), sclerosis (by itself), atheroma (by itself), and hypertrophy (by itself), can be easily diagnosed by a little consideration, yet more frequently, we have combined disorders and lesions.

Hypertonicity leads to sclerosis and hypertrophy of the media, and as age advances or some diatheses comes into play, atheroma is apt to be engrafted on the already diseased artery.

A case with hypertonic contraction in the presence of sclerosis, atheroma, and hypertrophy of the media, is often difficult of interpretation; but when such a case through some mischance, suffers a loss of tone in the muscle-cells of the blood-vessels, then indeed we have a puzzling train of symptoms, for no matter how diseased the artery may be, short of certain

freak cases, where the arteries are actually calcified, there still remains a possibility of pathological relaxation.

Having thus traced the functions of the muscle-cells of the heart according to the Gaskell and Mackenzie teaching, and having submitted my own classification of blood-vessel disorders, founded upon an extension of a recognition of these functions in the cells of the blood-vessels, I submit the subject to the meeting, hoping that those who follow may particularly trace the therapeutic indication of these theories; for, as I said in the beginning of my paper, it is the treatment of disease that most concerns the physician and the patient.

54 West Fifty-fifth Street.

EARLY TREPHINING FOR SEVERE INJURIES OF THE SKULL WITH A REPORT OF CASES OPERATED UPON.*

By M. S. KAKELS, M.D.

NEW YORK.

ADJUNCT ATTENDING SURGEON TO THE LEBANON HOSPITAL.

At the Lebanon Hospital, in the service of Dr. Parker Syms, all cases of severe injury to or over the vertex of the skull, with or without scalp wounds, are explored for fracture and all fractures are explored for depression. By severe injury is meant such cases in which the clinical history shows the traumatism to have been a violent one, and in which the symptoms, such as unconsciousness, pupillary reaction, vomiting, changes in character of pulse, and focal signs, have been present or exist at the time of admittance into the hospital. Cases in which there is a suspicion of injury to the cranium or its contents, even without lesion of the soft tissue and presenting no immediate symptoms referable to a lesion of the brain or its membranes, are held for observation, as it is well known that fracture as well as hemorrhage may exist even with the absence of typical signs.

In the course of two services, of a period of six months each, extending from November 1, 1907, to May 1, 1908, and November 1, 1908, to May 1, 1909, quite a number of traumatic injuries to the skull presented themselves. In speaking of traumatism to the skull, I include fractures simple or compound with or without depression, accompanied or followed by hemorrhage or inflammatory conditions of the brain or its membranes.

In some suspicious cases, later symptoms developed which required trephining and the operative findings showed the necessity of keeping such patients under strict observation.

It is true, patients with apparently trivial injuries to the skull and with no immediate symptoms, refuse to remain in the hospital and so we are not aware of the ultimate outcome of these. There is no doubt that a goodly number of such subsequently develop serious intracranial lesions and symptoms, as the literature abundantly shows.

In cases in which we have trephined for seemingly trivial injury, serious conditions existed either in the skull or its contents. In every case of trephining which we have made, the ultimate outcome, as regards operative interference and result, has been successful, and in no suspicious case did we regret making an exploratory operation. No case of exploratory operation ended fatally, developed meningitis or sepsis—in fact, every case ran a favorable course and was well at the end of ten days or two weeks, with primary union of the wound.

From our experience the expectant treatment of rest, purging, and local applications of cold, as taught in the text-books, is less advantageous, and does not give the same hope of relief or of saving life. We know today that severe cerebral injuries are amenable to surgical treatment, and therefore all cases of severe head injury, whether the diagnosis of fracture is made out or not, associated with grave cerebral symptoms, should be promptly subjected to operation as a safer course rather than the uncertain, hazardous expectant treatment. The immediate danger to a patient, after severe injury to the head, arises from compression due to extravasated blood; therefore, early relief should be instigated by means of the trephine.

Of the patients with compound fractures operated upon, only two died and in these the skulls were so crushed by the blows of a blunt weapon inflicted for the purpose of murder, that both frontal and parietal lobes of one side of the brain were lacerated and exposed to view by the large gaps made in the skull. In both these cases (mother and daughter) the injuries were on the left side and nearly similar in extent. Only the removal of the many fragments of crushed bone and excision of the lacerated brain tissue, with thorough cleansing, was made at the time of the operation. Both these patients were moribund when brought to the hospital, and both ultimately died on the fifth day from encephalitis notwithstanding the thorough aseptic treatment of the many and large wounds in the brain. The only other death in this series of 14 cases operated upon, was one in which I did a Cushing's subtemporal decompression operation, on both sides, with drainage for a simple bursting fracture of the skull involving vertex and base. The operation revealed an extensive fracture of the whole skull, with large epidural and subdural hemorrhages. My regret in operating in this case was only that I waited one week before I trephined for the relief of the pressure symptoms produced by the extensive hemorrhage. Perhaps if we had not waited so long the outcome might have been different. Cushing says "that in any serious cranial injury, in which unconsciousness has been present from the first, subdural bleeding is taking place either from the fracture itself or from some laceration of the brain. One cannot hope to disclose the oozing which may be taking place, but the chief indications in the face of compression symptoms are to bring relief by decompression and to furnish means of exit for the extravasating blood." One should not wait too long as delay in trephining is dangerous, because then the brain has been subjected to such pressure that destruction to its delicate cells and nerve fibers is inevitable. Continued increasing pressure leads to fatal anemia of the medulla. The results of all the cases of trephining which we have made, have shown us that insults to the brain and meninges by explorative puncture or incision, are well tolerated if done with strictest attention to aseptic precautions. Even extensive traumatic lacerations of the brain tissue are amenable to treatment. It is true that meningitis does not offer much hope to operative treatment, yet drainage is sometimes successful and not entirely hopeless, as one of our cases has shown, but, as said before, perfect asepsis in operation must be obtained by adhering rigidly to the most modern methods of surgical cleanliness.

*Read before the Medical Society of the Borough of the Bronx, November 10, 1909.

Technical skill and rapidity of operation are important requisites.

In operations for simple fracture with depression or with hemorrhage, the difficulties do not lie in gaining access to the cranial cavity, but frequently lie in the impossibility of making an exact preoperative diagnosis of the lesion. The diagnosis of fracture or laceration and hemorrhage, especially its extent; is more or less conjectural unless the injury is of such a nature as to allow inspection. Our results have shown that exploratory operations are not of doubtful expedience if one analyses accurately the history of the traumatism and the preoperative status and clinical picture of the patient.

In scalp wounds, with merely linear or fissure fracture without apparent depression, trephining has probably saved the patients from bad consequences, as many of these linear and fissure fractures of the outer table were complicated with comminuted of splintered fracture of the inner table. Infection and its consequences, meningitis and encephalitis, were more certainly stayed by operative interference. The elevation and removal of these comminuted and depressed pieces of the inner table prevent, in all liklihood, the development at some later time of epilepsy or other brain manifestations, for such symptoms do not always show themselves directly with the traumatism, but not infrequently are delayed. It is true that compression by blood or bone or laceration of the brain may be in some silent area and does not present focal symptoms at once, and thus, it may be said that where no exact or positive diagnosis of the lesion can be made, no operative treatment is rationally indicated. This is not altogether true. These are just the dangerous cases. The absence of immediate focal symptoms lull us into a false hope of security; meanwhile, changes of serious nature may be taking place in the interior of the skull. There is no doubt that there are many cases of depression of the inner table of epidural and subdural hemorrhage, presenting no immediate symptoms to warrant operative interference which presumably lead to spontaneous recovery. But there is no denying the fact that there are as many others which equally end fatally. Who knows that these presumably recovered cases will not have circulatory or destructive changes in the cerebrum in later life, due to the pressure sustained by the clot or depressed bone? The longer cerebral compression is allowed to continue, the greater the danger to the elements of the brain tissue. Pressure produces circulatory disturbances, causing hyperemia, then thrombosis of pial vessels, and ultimately degeneration of the cellular elements of the brain, with all its concomitant disturbances. This, therefore, makes the plea for instigating timely operative procedures the more imperative before such changes have taken place.

Medical literature abounds with cases in which patients have suddenly developed a change in their temperament from no assignable causes, or developed peculiar muscular twitchings or epilepsy, or have died suddenly, and the autopsy shows an old lesion of the brain or skull which, on careful inquiry into the past history of the patient, elicits some apparently trivial injury to the head that the patient had sustained sometime previously. Under such circumstances, the operative interference in all doubtful cases of depression of the inner table or hemorrhage is all the more impressive. There is no undue risk in trephining linear or fissure fractures, if strict aseptic precautions are taken. The *noli me tangere* principle may be followed by the development of focal symptoms years later. Blood clots may change to cysts. The pressure of cysts may lead to chronic cerebral irritation or fibrosis of the brain tissue, resulting in epilepsy or change in the mental condition.

That supradural or subdural compression is a contributing factor in the production of cerebral symptoms, is evident in many instances by the abeyance of these symptoms resulting from the elevation of bone or removal of clots.

Although the location of the hemorrhage, whether epidural or subdural, cannot always be directly established, yet the mere fact of trephining affords room for the expansion of the compressed cerebrum, and thus avoids compromising important vital vasomotor or respiratory centers. In recognized or suspected hemorrhage, there is no question about the necessity of operative interference. Procrastination is serious as death is imminent.

The few conditions resulting from traumatism either to the calvarium or its contents, namely fractures with or without depression, hemorrhage, serious effusion or laceration of the brain or its meninges, are therefore limited. The most important factors in determining us to make a presumptive diagnosis so that we may promptly arrive at a conclusion are: (1) History of severe injury to skull; (2) State of consciousness; (3) Condition of pulse and its rate; (4) The arterial tension; (5) The temperature; (6) Focal symptoms if patient is conscious; (7) Later headache localized or diffuse, and finally choked disc.

In our judgment, the majority of cases, with the history of severe head injury, with more than one of the above-mentioned factors, warrants operative interference if life is to be saved or future complications or sequelæ avoided. Of course, whether to operate early or to wait is a question upon which surgeons may differ. Is it more detrimental to the patient to operate than to wait for more urgent symptoms? Is there more risk from the shock of the operation than from the existing conditions? The indications are clear in many cases, but it is the border-line ones which tax our judgment. To wait until the onset of such symptoms, as are indicative of destructive conditions, adds only reproach to surgery, for then it is too late. One should bear in mind and recognize the serious consequences which may arise in unoperated cases, and appreciate the gravity of infection, of hemorrhage and pressure. A definite suspicion of intracranial lesion from our experience warrants exploratory operation. The institution of operative procedures immediately following the establishment of some lesion seems to me to be imperative. As said before, there is no undue risk in trephining, if strict aseptic precautions are taken. It is difficult and frequently impossible to distinguish clinically epidural from subdural hemorrhage or serous effusion, but each, to my mind, require trephining from the fact that the opening in the skull relieves pressure and affords room for the expansion of the compressed cerebrum.

Epidural hemorrhages are easily accessible, the operation for the same does not involve much risk, while the subdural ones are much more serious as they involve the greater liability of cerebritis and hernia, but the dangers of hernia and encephalitis from opening the dura are controllable and are

minimized by strict asepsis and careful closure of this membrane.

Recognizing and appreciating the serious risk of pressure from blood, bone, serous effusion, or edema of the brain itself, besides the great dangers of meningitis and encephalitis, relief should be early and promptly applied. The technique of craniotomy is simple and the cavity of the cranium can, under strictest asepsis, be invaded with as great impunity as any of the other of the body.

Having acted upon the statements and reasons, as set forth in this paper, it would perhaps be interesting to give a brief record of a number of cases operated upon, the findings of which conclusively proving that the operative procedures undertaken were in every instance indicated.

Case I.—J. P., aged 8, was admitted to the hospital January 11, 1908, with the history that half an hour before he was kicked in the head in the left temporal region by a runaway horse. He walked into the ambulance and on admission walked from the ambulance to his bed. He remembered everything and was not unconscious until an hour after admission. There was no bleeding from the nose, mouth, or ears. The pupils were equal, moderately dilated and reacted to light and accommodation. There was felt a slight depression about 1½ inches above and a little external to the left eye which extended upwards and backwards over a circular area about one inch in diameter. The skin was unbroken. Pulse was regular, fairly rapid, 100, temperature 98.6°, respiration 30. No paralysis, no loss of sensation, and lower reflexes normal. He vomited once in the hospital. One hour after admission patient had a tonic convulsion, lasting ten minutes, with head and eyes drawn to right and arms compressed against abdomen and legs drawn up. The convulsions were general.

Two hours after he received his injury I made a cross incision over the depression and found a comminuted, funnel-shaped depressed fracture, the fissures of the fragments radiating in every direction to a circumferential area, the diameter of which was about two inches. The depressed fragments had a larger circumference on their inner table than the outer ones and so were not easy to be raised. The fragments were carefully removed. The anterior branches of the middle meningeal artery and vein were exposed and some oozing from the dura was controlled by packing. There was an epidural clot which was removed. Some irregular elevation of the dura was noted and a small incision was made into it, liberating a considerable amount of clear cerebrospinal fluid, which was under such great tension that it spurted several inches into the air. The incision was then closed with fine catgut sutures. Most of the oozing had then ceased, but some blood still persisted to flow from some part of the middle meningeal vein which I controlled by passing through the dura a catgut ligature threaded on a small needle. Gauze drains were inserted and the scalp wound closed by numerous silk-worm gut sutures. The highest temperature was 100° and pulse 120 on the next day. The drains were removed on the fifth day and on the tenth day, an absolute primary union throughout the whole incision was found. There never was a symptom following the operation that indicated involvement of motor area—either irritation, muscular twitchings, or spasm. A noteworthy feature of this case is that we had to deal with a case of comminuted, funnel-shaped, depressed fracture of skull, with serous exudation under dura, without laceration of the brain, and without a lesion of the overlying scalp.

The boy made a perfect recovery. Had we waited and used the expectant treatment in this case, one can readily see what the consequences might have been. Constant oozing of blood without an exit would surely have produced fatal compression symptoms. Commencing intracranial pressure was evidenced by the force with which the cerebrospinal fluid was ejected after the incision into the dura.

Case II.—L. F., age 6 years, fell down a flight of steps, head first, and was picked up semiconscious and brought thus into the hospital. He did not vomit. The pupils were equal, moderately dilated, and reacted to light and accommodation. No hemorrhage from nose, mouth, or ears. Pulse was irregular, very rapid, of fairly good force and tension. On the head were found four scalp wounds, situated over the left parietal and occipital regions. There was a compound and depressed comminuted fracture of the vault near the posterior and upper border of the parietal bone; another compound linear fracture on the anterior part of the parietal bone; also a linear fracture from the depressed comminuted fracture passing down to the occipital bone where a compound stellate fracture was found. At the site of the comminuted fracture lacerated brain tissue presented through the wound as a hernia cerebri, about a teaspoonful being on the dressing. One hour after admittance I enlarged the scalp wounds by making cross incisions and by trephine and rongeur forceps removed the depressed spicula of bone over an area larger than a silver dollar. The protruding and lacerated brain (about a good-sized tablespoonful) was removed, the dura sewed over, and a small opening left for the insertion of an iodoform gauze drain. The other fractures were explored, cleaned, and drained, and the scalp wounds closed. Five days after the operation the scalp wounds were found to have healed by primary union, and three days later the drain to the brain tissue was removed, and the small opening allowed to close. At no time did the temperature rise higher than 100°. During the child's convalescence he showed absolutely no ill effects of the traumatism to his brain. His special senses were intact, he had no meningeal or cerebral symptoms, and from the time of his operation, January 21, 1908, up to the present day, no impairment of mental faculties. This I attribute to the lesion being in a silent area of the brain. The early operation, removal of spicula of depressed bone, excision of lacerated and protruding brain tissue, and free drainage, under strictest aseptic procedures, militated against infection and saved this little boy's life. It is conceded by all that in such conditions the only chance lies in early and prompt operation and thorough cleaning of contaminated brain tissue before infection has a chance to propagate.

This case illustrates that extensive lacerations of the brain and meninges are recovered from, if aseptically treated by surgical intervention, and shows that the brain is just as amenable to treatment as any other organ.

Case III.—On March 4, 1908, H. S., age 12 years, while on the third floor of a tenement, pulling up a dumbwaiter, received a blow from an iron bar which became detached from the top of the dumbwaiter-shaft and fell on his head. This so stunned him that he fell down the shaft from the third story to the basement. He was not uncon-

scious, bled profusely, was bandaged by a physician and sent to the hospital the next day. On admission the pupils were slightly dilated and reacted normally. He had a wound situated over the upper and posterior parietal region. At this point, a depressed fracture was made out. There were no cerebral symptoms. The wound was enlarged, and as the depression could not be raised, I trephined a little below the fracture and removed a small button of bone. The depressed bone was then cut away. The inner table was depressed and spicula of bone were found pressing upon the dura, so that with every pulsation of the brain the dura was subject to constant traumatism. These were removed, a gauze drain was inserted, and the skin flaps were closed. He was discharged cured, March 25, without an untoward symptom.

The condition found speaks for itself. Had this seemingly trivial depression not been explored, one can easily appreciate what the consequences would have been of a pulsating brain impinging constantly against the spicula of the depressed inner table. It also shows the importance of trephining every compound depressed fracture, no matter how slight the depression may be, or how insignificant the fissure may appear, for the slightest solution of continuity of the external table may be complicated by a larger or more serious fracture of the inner one.

Case IV.—F. A., age 39, was admitted November 24, 1908, with the history of having received various injuries in a fight in which the weapons used were a hatchet and razor. He was struck on the head and face with the hatchet. He was never unconscious and when brought to the hospital complained of pains over the wounds. He had no vertigo and did not vomit. His nose was completely severed from the face on the left side. The malar bone was broken but not splintered. The right side of the nose was intact. He had five scalp wounds on the head and lacerated wounds on the lip. The pulse was regular, of good force and quality. Pupils were equal and active, no twitchings or unconsciousness. Four of the wounds on the vault extended over the right side, one on the frontal bone, three on the parietal, the fifth over the left frontoparietal junction in the midline. The first wound was enlarged and found to be a compound depressed splintered fracture, situated on the posterior inner portion of the right parietal bone. The depressed fragments were removed with chisel and rongeur forceps. The fracture was an inch in diameter. Epidural clot removed. Dura not perforated and brain found pulsating. Gauze drain inserted to dura and scalp sutured to the drain exit. The second wound was in the middle of the right parietal bone, and was about three-quarters of an inch long. It was enlarged and a depressed splintered fracture found. The fragments were raised and dura found intact. Epidural clots removed, gauze drain inserted, scalp sutured to drain exit. The third wound was also about three-quarters of an inch long and situated over the outer posterior portion of the parietal bone, on the right side. This was enlarged, but no fracture found. The fourth wound was found extending from the left posterior middle part of the frontal bone to the inner anterior part of the right parietal bone. The vault was found to have had a fissured fracture involving the outer table only. Rubber tissue drain inserted. The fifth wound was over the right posterior portion of the frontal bone, about an inch long; it was enlarged and the vault showed a fissured fracture, also only of the outer table, which was explored. The scalp was sutured, with insertion of rubber-tissue drain.

This patient made a good recovery. The wounds healed by primary union, except at site of drain, which, when removed, closed speedily. The patient was out of bed and well after the tenth day and discharged cured.

Case V.—D. P., age 28, in a fight with the previous patient, whose case is recorded, was admitted at the same time, namely, November 24, 1908. He had two razor cuts on left side of neck, each about three inches long. The vault contained three scalp wounds: One in the posterior portion of the right parietal bone, about one inch long; another through the middle of the sagittal suture and another over the mid-anterior part of the left parietal bone. The pulse was regular and of good quality. The pupils were unequal; there were no twitchings or loss of consciousness.

The posterior wound was enlarged and a depressed comminuted fracture, about one inch in diameter, found. The depressed fragments of the stellate fracture of the inner table lifted from the underlying dura. Epidural clots removed and dura found intact.

The middle wound, just above the longitudinal sinus, was one and three-quarter inches long. It was enlarged and the vault found fractured and depressed to an area of one and three-quarters of an inch. A small piece of metal, wedged tightly, was gradually chiseled from the whole thickness of the skull, and when lifted out was found that it penetrated the dura. This piece of metal was a broken sharp edge of an axe, and measured about one-quarter by one-half an inch. The depressed fragment of the outer table was raised and the inner table found to have sustained a comminuted depressed fracture. The fragments removed and dura found perforated, gauze drain inserted, and scalp wound sutured.

The anterior wound was enlarged and skull found depressed at both outer and inner tables, to an extent of about three-quarters of an inch. Depressions were raised and fragments removed. The dura was exposed, clots were removed, a drain was inserted, and the scalp was sutured.

This patient, like the previous one, made an excellent recovery. The wounds all healed by primary union except where drains were inserted, but which also promptly closed when they were withdrawn. This patient was out of bed and left the hospital at same time as the other one. At no time did either of these patients show any disturbance of motor or sensory functions, neither did either show any meningeal symptoms notwithstanding the numerous and multiple depressed fractures pressing on the meninges. The tolerance of the brain and meninges to the numerous insults produced by the multiple depressed fragments and foregn body was apparent in these cases, but there is no doubt that the prompt and thorough aseptic operative interference contributed not a little to the successful outcome of both these cases, for pressure was relieved, the dura repaired and drained, and that bugbear of all operative procedures, infection, certainly prevented.

Case VI.—On December 31, 1908, while at play, J. G. was shot in the forehead by a 22-caliber revolver. He was immediately brought into the hospital in a semi-comatose state, with apathetic facies. The eyes were normal, no inequality of the pupils, no subconjunctival hemorrhage, and no convulsions. His reflexes were normal; the pulse 100, of fair

force and regular. A little to the left of the median line, over the nasal portion of the frontal bone, was a small perforated wound, about the size of a pea, from which there exuded blood and a whitish-gray substance, presumably brain matter. There was no other wound in the skull. An aseptic dressing was applied. On the next day, January 1, pulse became irregular, and patient was drowsy during the whole day. On January 2, in the morning he seemed brighter, but in the afternoon became drowsy again. On January 3, he was restless, but seemed a little brighter and talked several times. Meningeal symptoms then commenced to show themselves. He was very restless during the night, complained of severe pains in head and neck. Temperature 101°, pulse 56, respirations 28.

On January 4, the boy was drowsy, had flushed face and complained of pain in gluteal regions. Pulse irregular. He was then seen by Dr. Syms and by Dr. Leszynsky, neurologist to the hospital. There was no evidence of paresis. There was slight rigidity of the posterior cervical muscles. Both knee-jerks were slightly accentuated and Kernig's sign was well marked. Plantar reflexes normal. Visual field normal. Temperature 103°, and evidence of meningitis being well marked. At the suggestion of both Dr. Syms and Dr. Leszynsky, it was thought wise to trephine the original wound of entrance so as to drain more thoroughly. Accordingly, it was enlarged to about two inches and a one-quarter inch perforation exposed in the frontal bone. Small spiculæ of bone were removed by gouge and chisel. In doing so there was a sudden gush of dark blood in a steady stream; no spurting and supposedly an accessory straight or longitudinal sinus was perforated. This was quickly packed with iodoform gauze, which also acted as a drain for the laceration in the brain, and a dry sterile dressing applied. From that time on his temperature dropped until the 15th day, when it was practically normal, while during this time all his meningeal symptoms gradually disdisappeared. He was kept in the hospital, however, for observation until February 12. The bullet is lodged, as one can see from the radiograph, in the cerebrum, and has in this situation never produced in the boy the least changes either in his mental faculties or special senses, nor caused any motor or sensory disturbances.

It is very remarkable that a 22-caliber bullet, passing through the brain, should produce no focal symptoms or leave any permanent defect. To attempt to remove this bullet while it is lying in this silent area, where it is causing no disturbance, may produce more harm, by hunting for and extracting it from normal surrounding brain tissue, than it is doing in its quiescent state. Small foreign bodies, it is well known, have become encysted in the brain and have remained there without causing the least disturbance to cerebration. The boy goes to school, is carefully observed, and should the slightest evidence of any effects of the foreign body show themselves, operation for the removal of the same would then be imperative. I think this case can be regarded as a triumph of surgical intervention for the relief of an incipient meningitis.

Case VII.—On the day of admission, February 20, 1909, J. S., age 13, was struck by a truck while roller-skating and thrown to the ground with quite some violence, his head receiving the brunt of the fall. He was picked up unconscious and brought in this state to the hospital in the ambulance. There was no wound on the scalp. The pupils were unequal, the left contracted, they reacted to light, but not to accommodation. There was no subconjunctival hemorrhage. The boy was pale, his respiration superficial and sighing. Pulse slow, full, and bounding. Kernig's symptom was present on both sides and slight rigidity of neck muscles was apparent. The next day patient was very restless, and had to be catheterized. The pulse and unconsciousness not improving, and finding a small area at the junction of frontal with the parietal bone, which felt like a depression, an exploratory incision was made over this region. The incision was about two inches to the left of the sagittal suture. The bone was exposed and a depression about the size of a silver dollar was found, which was trephined, and the depressed bone removed. Pulsation of dura was evident. From this depression fracture a fissure fracture, 1-16 inch wide, extended posteriorly to the occipital region, from which there was quite a deal of bleeding. An incision was made in the dura, but no subdural hemorrhage found. It was closed with interrupted catgut sutures and a rubber tissue drain placed over the whole length of fissure fracture, and a gauze drain over the dura incision. The next day the boy was restless, but took nourishment, and seemed brighter towards evening. For the next few days was noisy and restless, but responded when spoken to, and on February 24 voided voluntarily for the first time. From now on the cerebral symptoms gradually improved. On February 26 wound was dressed. On February 28 signs of croupous pneumonia were evident. This complication ran its course, with high fever, until crisis set in on the ninth day. On March 11 the wound was found entirely healed, and only for a little weakness, the boy was entirely well and made a perfect recovery, both from his craniotomy and complicating pneumonia.

Immediate explorative incision of the scalp, in the region of the injury, revealed a depressed and fissured fracture, from which there was quite a deal of hemorrhage which had no outlet. In spite of the absence of a lesion in the scalp, infection may have taken place (especially in this case by the pneumococci), with all its dire consequences. In severe traumatism to the skull, one should not ignore the possibility of a fracture over a suspicious spot, for, in many cases, there will be revealed on the exposed skull a serious lesion. Drainage, no doubt, sufficed to ward off the consequences of the systemic pneumonic infection.

Case VIII.—Nicholas B., age 14, on February 26, the day of admittance to the hospital, was hit by one of his playmates, with a stone about the size of a brick, which struck him with extreme force on the left side, back of his ear. He fell to the ground, but immediately rose and ran to a physician who sent him to the hospital. He was never unconscious or irrational, and remembered all that occurred. There was quite some hemorrhage from a gaping wound, which was on the scalp, in the left occipital and temporal region. Through this wound there was felt a depression of the skull. There was no bleeding from nose, mouth or ears. The pupils were equal and reacted normally. There was no rigidity. Pulse full and bounding. No Kernig, no ankle clonus.

The wound in the scalp was enlarged by cross incisions, and a depressed, splintered fracture, about the size of a quarter of a dollar, was found. Dirt, small bunches of hair and lacerated pieces of scalp were removed from the lacerated brain

and six loose fragments of bone which had been driven into the brain substance proper, to a depth of about one-half an inch, by the force of the blow, were removed with forceps, after the skull wound had been enlarged with rongeur forceps. There was quite some hemorrhage, which was easily controlled by compresses. An iodoform drain was inserted and scalp wound closed to the drain.

The boy made an uninterrupted recovery, was sitting up in bed reading a book the next day after the operation without the slightest rise of temperature, and was discharged absolutely well at the end of two weeks. The successful outcome must be attributed to the early operative interference, thorough cleansing and removal of all foreign substances, with thorough and adequate drainage, thus eliminating as far as possible all source of infection. Extensive, lacerated wounds of the brain, even when contaminated—such as the one above recorded, are just as amenable to prompt surgical intervention as extensive injuries to other tissues of the body.

Case IX.—Louis G., age 30, admitted March 29, 1909, with the history of having fallen off the seat of a wagon, striking his head on the ground. He was unconscious, and was in this state when brought to the hospital in the ambulance. There was a hematoma on the left side of the scalp. The pupils were equal and reacted to light only. There was no hemorrhage from the ears, nose, or mouth, or ecchymosis under the eyelids. The pulse was 42, bounding, and of high tension. He vomited twice, was very restless. Ankle clonus and Kernig's sign were present. This unconsciousness continued all day. The pulse remained low and restlessness increased. At 9 P.M., a horseshoe incision was made over the region of the hematoma, and the flap retracted. The coronal and sagittal sutures were found burst asunder to about 1/16 of an inch, with blood oozing from the separated bones. The beginning of a fissure fracture was found in the right parietal region, about three inches behind the frontal bone. In order better to expose this fracture, an incision in the scalp was carried across the right side anteriorly, also one posteriorly, the flap retracted, so that the right parietal bone could be exposed. The fissure fracture was then seen to start at and running at right angles to the sagittal suture, across the parietal bone. The skull was trephined over this fissure at about three inches from the midline and an epidural clot found. The bone was bitten away, so that an exposure of about 2½ inches long and 1½ inches wide was made. The large epidural clot was about 1/16 of an inch thick. This was removed as far as possible from under the edges of the large defect. Dural pulsasations were observed. It was, nevertheless, incised, no blood escaped, but instead free cerebrospinal fluid, under quite some pressure, spurted from the incision. The dura was then closed with interrupted catgut sutures. Two small rubber tissue drains, placed on dura, one in the lower and one in the upper corner of the wound. Dura covered with iodoform gauze drain, and scalp sutured.

The next day the patient was very restless, vomited, and voided involuntarily. Towards evening he became quieter and was rational for a short time. His pulse ran between 52 and 64. The second day after the operation he recognized his wife and responded to questions. During the next few days the pulse ranged from 56 up to 80, he became gradually brighter and gradually regained his normal mental condition. On April 5 the dressing was changed, and wound found healed by primary union. Outside of a headache the man never had a focal symptom, and was discharged well, May 1.

Complete and continued unconsciousness, with a slow pulse and history of severe traumatism to the skull, were indicative symptoms to explore over the hematoma. A separation of the coronal and sagittal sutures—in other words, fracture by diastasis, is rare. In adults it is more than a separation, as the union is firmer than in the young and separation cannot occur otherwise than by a break. Thus, this was an extensive bursting fracture of skull, with epidural hemorrhage, and was only revealed by exploratory operation. From the history and clinical symptoms present, no one will question the propriety of an exploratory operation in this case.

Case X.—Geo. N., age 11, on April 5, 1909, while playing in the street, was struck by an automobile which threw him to the ground. His head struck the pavement with considerable force. He remembered nothing following the immediate accident. He was unconscious up to one-half hour after having been brought to the hospital by the ambulance. About an hour after this he developed a convulsion. Both arms and hands were involved in the convulsive movements. After persisting for about half an hour they subsided, to be succeeded by intermittent contractions of the right upper extremity. The lower limbs were not involved. He regained full consciousness about three hours after admission. There was no bleeding from nose, mouth, or ears. The scalp showed no laceration. A hematoma, situated at the left parietal and frontal region about the size of a goose egg, was found. No depression could be made out. The pupils were equal and reacted to light only. No subconjunctival hemorrhage, no rigidity of neck. There was slight ankle clonus and Kernig's symptom was present. He vomited a few times, the vomiting being projectile in character. After regaining consciousness, he was fully aware of his surroundings.

From the history and clinical symptoms, four hours after his injury, I decided to make a local scalp exploratory incision. An incision was made over the hematoma. A fissure fracture was discovered, extending from about the fissure of Rolando anteriorly across the coronal suture to the frontal eminence. The bone was trephined about one inch to left of median line and one inch anterior to the coronal suture, and a button of bone removed, about the size of a silver dollar. The dura was found bulging and not pulsating. It was opened by an incision, one inch long, running downward and outward. There was escape of free blood, a little darker than arterial blood, and a small clot removed from the surface of the brain. The dura was closed with fine interrupted catgut sutures and a rubber tissue drain inserted to the brain under dura. Dura was covered then with an iodoform gauze drain, and both it and the rubber tissue drain were drawn through a counter opening in the scalp, and another rubber tissue drain placed along the course of the fissure fracture; the scalp was sutured. The next day ecchymosis and swelling around left eye appeared. The boy looked drowsy, but had no focal symptoms. He vomited twice. The day following ecchymosis and swelling around right eye appeared. Subconjunctival hemorrhage was now evident. Temp. 100.2°, pulse 100.

On April 9, the drain from the brain was removed. From this day on the temperature gradually dropped to normal and pulse never went higher than 96. He was perfectly rational, slept and ate well, and on

April 12, seven days after operation, all sutures were removed, and primary union obtained. At the end of two weeks patient was out of bed, walking around perfectly well. Notwithstanding the fissure fracture of the vault, with subdural bleeding, and clot and fracture at the base in the anterior fossa, as evidenced by ecchymosis and subconjunctival hemorrhage, the boy never had any further evidence of interference in cerebration, neither did he show any further focal symptoms, either motor or sensory.

Early operation in this case evidently shows that the removal of a subdural clot and drainage of the subdural space caused an abeyance of the irritation to the motor tract over which the hemorrhage had taken place. The blow to the cranium must have torn some pial vessels causing the hemorrhage, and had not relief been early instigated for drainage and control of the hemorrhage, increased bleeding would, in all likelihood, have caused increased pressure over a larger area of brain and compromised more motor centers, with probably irritation and finally irretrievable destruction of the same. Exploratory scalp incision revealed a fracture. Exploration of the fracture revealed a bulging of the dura. Exploration of the dura revealed a subdural hemorrhage and permited its control.

All these explorations, under aseptic precautions, were safe, and the positive findings certainly demonstrated the value of early trephining. We not only were able to save the life of a patient, but probably averted future paralysis and changes in temperament or disposition.

There was another case in this series, operated upon with recovery, but as the fracture only involved the outer table of the frontal bone, produced by the kick of a horse, the case is not recorded as the cavity of the skull was not invaded and the brain not exposed by operative procedure.

That none of these cases became infected, must be attributed to the absolute adherence to the strictest rules of aseptic surgery. Apparently the good results were to a great measure obtained by the rapidity of operation, by the control of hemorrhage, and, especially in the compound fractures, by prompt intervention, with more than thorough cleansing of the wounds.

While it is true, in a great many cases of severe traumatism to the skull, intracranial lesion may be presumptive, and though it would seem that an exact knowledge of what is to be encountered is essential before trephining ,from our experience the value of an explorative incision nevertheless has not been overestimated and cannot be gainsaid, even though the nature of the cranial lesion was conjectural.

The propriety of exploring fractures of the cranial vault, by incision of the soft parts and elevation of bone, if depressed, is conceded by the majority of surgeons. In compound fractures, exploration is positively indicated. In presumptive simple fractures, with a history of severe trauma, whether a depression is felt or not, whether there exists a hematoma or not, and with general symptoms, such as the state of consciousness, character of pulse, temperature, and respiration, accompanied with muscular or nervous symptoms, expectant treatment, to my mind, is hazardous.

I do not wish it to be understood or believed that I advocate the indiscriminate use of the trephine in every injury to the skull.

A survey of the cases reported and their results fully bear out the opinion as expressed in this paper that an early exploratory operation is indicated in every severe injury to or over the vertex accompanied by such symptoms as would lead us to presume that there may exist a lesion either of the skull, or, what is more important, its contents. We must always bear in mind that in considering severe injuries to the skull, it is to the more serious lesions of its contents which so frequently accompany them that importance must be attached rather than to the fracture itself.

71 East Sixty-sixth Street.

CANCER OF THE FEMALE BREAST.

By JABEZ N. JACKSON, M.D.,

KANSAS CITY, MO.

Statistics seem to indicate that the prevalence of cancer is continually on the increase. It is stated that the annual death rate from cancer in England is to-day four times as great as it was fifty years ago. And this despite the fact that millions of dollars have been expended on laboratories for cancer research and the entire lives of many of the ablest and most scientific investigators in our profession have been devoted exclusively to this problem. Some day perhaps in the golden future the secret will be solved and this scourge will yield as others have yielded and are yielding to the banishing dictates of preventive medicine. As yet to-day, however, we must contend with its increasing prevalence and bend our efforts as practicing physicians and surgeons to secure a cure of that which we are as yet powerless to prevent. Even here, alas, our efforts are too often of little avail, though year by year, with increasing thoroughness of work and earlier recognition of the disease, our results are showing greater encouragement.

Next to the uterus the mammary gland is of all organs of the woman most prone to malignant disease. And here likewise, should be the most favorable field for early recognition of the disease and accordingly earlier institution of radical therapeutic measures. The mammary gland being the most superficial glandular organ and subject ever to much attention and observation, affords great opportunity for the earliest possible recognition of the beginning of any diseased process, and a correct diagnosis of its pathological character.

At the very outset it is of the utmost importance to remember that from 80 to 90 per cent. of all tumors of the breast are malignant. According to Billroth's statistics embracing 440 cases, eighty-two per cent. of all tumors of the breast are cancer. Schmidt, of Heidelberg, found 82.66 per cent. malignant; Bryant, 83.16; Gross, 82.47. The author of the chapter on breast tumors in Von Bergmann's "Surgery" states that in his clinic of 359 tumors of the breast, 306 were carcinoma or 80.9 per cent.; 34 were sarcoma, 9.1 per cent., making the net percentage of malignancy 90 per cent., while but 19 of the series were benign growths. Jonas, of Omaha, in a recent report embracing 260 cases from his experience, found 218 cases or 87 per cent. malignant and 42 or 13 per cent. benign.

When it is further remembered that many cases apparently benign at the outset finally undergo or manifest malignant development the figures become most impressive. C. H. Mayo in his clinic tersely remarks "that 80 per cent. of all breast tumors are primarily malignant; that of the remaining 20 per cent. of primarily benign growths, one-half ultimately become malignant, raising the final percentage of malignancy to 90 per cent., and that the

remaining 10 per cent. must be viewed with great suspicion."

The correct diagnosis of breast cancer is therefore of vast importance, and to the first attending physician one of gravest responsibility. For as William Francis Campbell of Brooklyn has so forcibly said, "Given a patient with cancer of the breast in the first stage, consulting a physician on its first detection, the fate of that woman is in the hands of the doctor whom she first consults, provided she follows his counsel."

Of much suggestiveness at the outset are certain general etiological facts pertaining to cancer of the breast. (1) Age: Cancer of the breast is, generally speaking, a disease of middle life the average age according to Crile being 49. The complete statistics of the Massachusetts General Hospital show, of a total of 309 cases, 5 occurring between the ages of twenty and thirty, 56 between thirty and forty, 120 between forty and fifty years, 107 between fifty and sixty, and 21 between seventy and eighty. It is also noteworthy here that, while cancer of the breast is quite rare under thirty, yet it does occur. On the other hand it is quite probable that most malignant tumors show themselves at an early age in the woman's life. Indeed I feel that we may generally assume that a tumor in the breast of a woman under thirty years of age except with pathognomonic evidence of malignancy, is probably benign, while after we pass this age the probability of cancer becomes so much greater that we will be much safer in assuming malignancy as a fact. (2) Heredity, on which in the past much stress has been laid, is of little importance and in only about one-third of our cases can a hereditary history of cancer be found. (3) Lactation factors likewise are of little significance since, according to Crile, 35 per cent. of his cases had not borne children and in but 11 per cent. was there distinct a history of lactation complications. It is quite probable, however, that chronic mastitis has something to do in producing a favorable nidus for cancer as is true in chronic inflammations elsewhere. (4) Injury likewise has some influence but is of too little importance to be significant. In fact it is too easy to find a history of injury antecedent to any condition to which the human flesh is heir, if we but ask for it.

Giving whatever weight we wish, however, to etiological factors, we are finally forced back to physical findings for correct diagnosis in a given case. It is undoubtedly a fact that almost without exception the finding of a tumor in the breast is the first sign that calls the patient's attention to the existence of disease. This was true in 94 per cent. of Crile's cases, while subjective symptoms such as pain, tension, stinging, etc., preceded in but 6 per cent. It is furthermore worthy of note that in but one-third of these cases was pain a symptom at all while two-thirds of them were free from pain. This should warn us forcibly against the folly of waiting for pain as an evidence of cancer. It is generally a quite late symptom, one only manifest often when the disease has so far advanced "that a wayfaring man, though a fool, could not err" in diagnosis.

Palpation, therefore, becomes probably our most accurate recourse in diagnosis. The intelligent manipulation of a hand trained in the sense of touch becomes therefore of paramount importance. For the exercise of this faculty it is essential that the flat of the fingers and palm of the palpating hand should be pressed gently down upon the breast and the tumor thus defined between the hand and the unyielding chest wall behind. Pinching up the breast between the fingers has doubtless led to many fallacies, oftimes I am sure leading to the removal of mammary glands in which there was actually no disease present whatsoever. When we remember that the breast is a lobular organ, it follows that in pinching up a breast, as I have seen many do, we can find an apparent tumor, certainly a mass in all. With the hand or fingers flatly applied to the chest, however, and gently compressing the breast between it and the bony wall, then moving the breast beneath horizontally over the underlying ribs with the skin fixed by contact with the hand, any existing tumor even though small can be detected with surprising ease and accuracy. The nodule may be exceedingly small, yet the stony hardness of a cancer growth will be striking and characteristic. Careful comparison in all manipulations should be made with the healthy breast, though here it should be remembered that bilateral disease, while infrequent and therefore improbable, is not impossible. A carcinomatous tumor is generally single, and multiple tumors speak agansit malignancy. The cancerous growth likewise infiltrates the normal breat tissue, and this not being circumscribed, it moves with the breast in which it is definitely fixed. It is also quite apt to become fixed early either to the skin overlying in superficial growths, or to the pectoral fascia beneath in deep-seated growths. The skin attachment is easily recognized. The facial attachment may only become evident when the arm is carried upward and outward, rendering the pectoral muscles tense. Then oftimes the tumor and with it the breast becomes absolutely immobile on the chest wall. "Dividing the breast into a central or areolar portion and four quadrants, we find the frequency of location in the following sequence: Upper outer, central, upper inner, lower outer, lower inner." It is also important to observe the relative amount of normal gland remaining outside the area of the tumor. Inasmuch as the cancer grows at the expense of the breast, and fibrous tissue contraction accompanies the process, there is oftentimes but little normal gland tissue left. The extent of this ratio is oftentimes also an evidence of the rate of growth which may be of service in prognosis as well as in diagnosis. In simple tumors, on the other hand, the normal breast tissue is pushed aside but not consumed.

The tendency of the fibrous tissue trabeculæ to shorten and thus to fix the breast, may also give visual evidences even at a very early stage of the disease, in the slight dimpling of the overlying skin evidenced by moving the breast over the chest wall, producing also a sensation of tugging to the examing hand. Halstead especially lays great stress on this sign, even going so far as to say that "the faintest conceivable trace of a difference on the two sides in a minor pectoral crease, for example, may suffice for the diagnosis. Frequently there is no sign, but this almost imperceptible suggestion of pull which, when the faintest possible, is, of course, elicited by dislocation in one direction only. This sign, however slight, is all that is needed for the diagnosis." Surely, however, we must remark, extreme care must be taken in this test, and only an experienced examiner of breast tumors could follow the refinement of Halstead's test in its entirety. When well developed, however, it is surely trustworthy. Minute comparison of both breasts is, of course, essential.

The sign of retraction of the nipple on which so much reliance was formerly put, is not now given

quite so much prominence. In some subjects it will be found that this characteristic is found normally and is then present in both nipples. When present in one nipple alone it is still a highly significant sign. Its absence, however, is of little value in negating a diagnosis. In fact, Crile found it present in only 33 per cent. of his cases. It must be remembered that this sign is likewise dependent upon shortening of the trabeculæ, and unless the growth is in the central area or quite near the nipple, no retraction will occur except in a large or well-advanced cancer.

The fat overlying a cancerous nodule, if it be superficial, is oftimes absorbed, also lessening the freedom with which the skin moves over the tumor and oftimes making the tumor stand out so prominently as to be at once apparent to the inspecting eye. In early diagnosis, particularly in that of deeply seated nodes, it is valueless.

The involvement of the axillary glands and their enlargement comes sooner or later, alas often too soon. It is to be remembered that acute inflammations, tuberculosis, etc., can likewise produce enlargement of the axillary glands. The local evidences of infection and inflammation, however, are usually so easily recognized in these diseases as to lead to no confusion in their differential diagnosis. With these inflammatory causes set aside the evidence of enlarged axillary glands is quite conclusive of cancerous disease. In fact, the diagnosis should be made before this symptom is evident.

As to the evidence of ulceration, emaciation, and cachexia, we will only say that they are such late evidences as to be of no service to a clinician. By the time these symptoms are manifest a housemaid could make a diagnosis.

Finally as to diagnosis I would say with Crile, "An indurated, invading, solid, somewhat irregular mass when gently pressed against the breast, with or without retraction of the nipple, with or without discharge from the nipple, with or without absorption of fat over the tumor, with or without dimpling, with or without pain, with or without hereditary history, with or without cachexia, ulceration, or metastasis, should be treated surgically, either explored or excised.

After, however, all is said as to physical diagnosis, and all the various diagnostic signs have been fully exhausted, we must yet admit the fact that in many cases preoperative absolute diagnosis is impossible. This is particularly true in the earliest stages of the disease. And here is to be found, therefore, the somewhat plausible excuse for a course of hesitation, palliation, and delay, so fatal in the end to the fate of the unfortunate woman. When, however, we reflect that even a benign tumor never disappears except by removal; when we remember that from the aspect of general probabilities alone the chances are nine out of ten in favor of malignancy; when we realize that a simple incision will make a diagnosis absolutely clear, is there then left any possible excuse for the responsble physician to counsel a course of procrastination which, as we shall later see, probably robs the sufferer of one-half her chances of life? Certainly not. Exploratory diagnosis must, therefore, in doubtful cases be insisted upon. If the tumor prove benign, without harm or risk to the patient in the least, local excision alone has at least removed a source of menace which should be removed anyway.

On the other hand should the evidences of malignancy be found, the operator should be prepared to push his operation at once to immediate complete amputation. With Bloodgood we believe that the experienced surgeon should have relatively no difficulty or doubt in the diagnosis of cancer after incision from the mere gross appearance of the tumor tissue. If in doubt, however, a competent pathologist must be at hand for immediate microscopic diagnosis from the frozen section, a proceeding which adds exactness with a delay of less than ten minutes at the farthest. We cannot too strongly condemn the policy of excision, delay for fixed specimen diagnosis, and secondary operation once in vogue, since Halstead has shown that in cases of cancer of the breast where this course has been pursued not one single case has ever been finally cured. Fortunately immediate diagnosis is now the practice of all operating surgeons, and such fatal mistakes will not occur.

Once an absolute diagnosis is made or even a probable diagnosis, the treatment becomes the responsible question between patient and physician. Is it too much to say to-day that radical surgical treatment is absolutely the only treatment? Certainly no physician to-day would for a moment consider salves, caustics, or local applications of like nature, methods now happily employed only by absolute ignorance or quackery. Thus far, moreover, the writer has never known nor heard, nor read in scientific literature of a single case of breast cancer cured by the *x*-ray. Injection of trypsin or allied preparations have not a single record of cure to their credit. It is, of course, easy to find reports of cases where from such various methods temporary shrinkage or apparent disappearance of the growth has occurred. But does this prove a cure? Volkmann many years ago established the dictum, since universally recognized in surgery, that to class a case of cancer cured at least three years must elapse with absolutely no evidence of recurrence either local or remote. Even this limit is oftimes transgressed in apparent safety with yet later recurrence until to-day we are rather inclined to push our limit of time standard forward to five years. If this be the criterion by which the cure of cancer is to be measured, how ridiculous the often bombastic claims of methods based on apparent results of but a few months' test at best. Undoubtedly all honest surgeons look forward with earnest hope to some time when we can cure cancer of the breast without the horror of the knife. Likewise undoubtedly most all honest physicians admit that up to the present hour there is nothing but surgery which offers the faintest hope of success.

At this point possibly the patient or her sceptical attendant will ask: "And what can surgery offer?" I must confess that during many years of our earlier work, before accumulative evidence was at hand, our answer would needs have been, faith. But time and evidence have converted faith into very encouraging facts, some of which I beg now to record.

Halstead, reporting the final results in 210 fully traced cases from the records of Johns Hopkins Hospital, all passed the three-year period of time since the operation, shows 89 permanent cures, a percentage of 42.4 in detail as follows:

Pathological Variety	No. Cases	No. Cured (3 years)	Per Cent.
Cancer cysts	6	2 (1?)	33.3
Adenocarcinoma	32	24	75.
Medullary carcinoma	25	12	48.
Circumscribed scirrhus	28	13	46.4
Small infiltrating scirrhus	80	30	35.5
Large infiltrating scirrhus	39	8	20.5
Total	210	89	42.4

It is furthermore worthy of note that from this gross number there were 60 cases operated upon in which there was no glandular metastasis, and of this number 45 (75%) were permanent cures and 51 or 86 per cent., were free from recurrence on the three-year limit. This clearly demonstrates the absolute importance of early diagnosis and early operation whereby the chance of cure is absolutely twice as good.

Glandular Involvement	No. Cases	Permanent	Per Cent.	3 Years	Per Cent
Axilla and neck negative....	60	45	75	51	85
Axilla positive, neck negative	110	27	24.5	34	31
Axilla and neck positive.....	40	3	7.5	4	10

In the Massachusetts General Hospital, Boston, between the years 1894 and 1898 inclusive (first five years), there were 160 cases operated, of which 26 were cured, or 16.2 per cent. In the years 1899 to 1903 (second five years), of 157 cases 41 were cured, or 26 per cent., almost double the percentage of the first five years, surely a convincing evidence of improving results. Here also we find that whereas the percentage of cures where the axillary glands were enlarged was but 12 per cent., when the axilla was negative the percentage was 29.

Pathological Variety	Cases	Surviving Operation	Cures	Per Cent.
Medullary.....	136	104	19	18.2
Scirrhus.....	46	43	10	23
Adenocarcinoma.....	24	21	10	47.6
Colloid.....	4	3	2	66.
Cancer.....	127	107	18	16.8
No. pathological report.	39	31	8	25.8

Crile of Cleveland, in a traced record of 91 cases, found that in cases with glandular involvement his percentage of cures was 14 per cent., while in cases where no glands could be found prior to operation his percentage of cures was raised to 80 per cent.

Cabot of Boston, in an experience of 42 cases has had 9, or 21 per cent. of cures.

Dennis of New York, in a series of 116 cases reported before the American Surgical Society in 1891, showed 45 per cent. of 3-year cures. In 1895, in the report of a smaller series to the same society, he recorded 77 per cent. of cures.

Willy Meyer of New York, in a series of 80 cases reported 28, or 35 per cent. of cures. Of these there were 16 cases operated on, 10-12½ years, of which 3 (18.75 per cent.) are alive to-day; 27 cases operated on, 5-10 years, of which 6 (22.2 per cent.) are alive to-day; 20 cases operated on, 3-5 years, of which 10 (50 per cent.) are alive to-day; 17 cases operated on during the last 3 years, of which 9 (50 per cent.) are alive to-day.

Vander Veer of Albany, N. Y., in a series of 103 cases reports 70 cured, or 68 per cent.

Ochsner of Chicago, in 98 fully traced cases, reported 54, or 43 per cent. cured.

Oliver of Cincinnati, of 35 cases, reports 12 cured from 3 to 10½ years, or 34 per cent. cures. Here also we learn that in cases where the tumor has been known to exist for one year or more, the per cent. of cures was 28.5, whereas in cases where tumor had existed over from 6 months to one year the percentage was 50.

Jonas of Omaha, in 177 traced cases, found 105 cured 3 years, or over 56 per cent.

Rodman of Philadelphia, reports that in cases from his private practice 70 per cent. were cured.

Cheyne of England, in 34 private cases had 17, or 50 per cent. of cures alive after 6 to 16 years.

Childe, in 46 cases, had 17, or 36 per cent., well after from 5 to 20 years.

Dowd's analysis of 199 cases from the clinics of Bull, Rotter, Helfreich, Cheyne, Dennis, and May shows 39.6 per cent. cured.

A summary of this rather extended evidence shows a percentage of cures ranging from 25 per cent. at the lowest to 75 per cent. at the best. This, in a disease otherwise absolutely fatal, is certainly most encouraging, and has furnished a magnificent proof for the faith in surgery. Two other facts likewise stand out prominently. First, that in cases of early diagnosis and early operation the percentage of cures is practically doubled. Surely the responsibility resting on the first attendant is enormous. Second, the results in private cases are vastly better than in those selected from crowded tenements of pauper population. Have we not, therefore, particular ground for encouragement with a class of patients to whom fresh air, glorious sunshine, and good food is not a luxury but an every day possession.

But perhaps again some doubting Thomas or some timid subject may inquire, Is there not great risk to life in a formidable surgical procedure which furnishes such results? To this we reply, Halstead had but 4 deaths in 232 cases, 1.7 per cent. mortality. Crile in 91 cases had no deaths. At the Massachusetts General Hospital in 416 cases operated on by over twenty various surgeons, there was but 3.6 per cent. mortality, and in the later years (1899-1903) but 2 per cent. Cabot in his 42 cases had no deaths. Ochsner had 5 deaths in 164 cases. Jonas had 6 deaths in 255 cases. According to Haggard, in the analysis of 600 operations in the hands of twenty-one different surgeons, the mortality was but 9 per cent. The writer in his personal experience has had no deaths from operation nor has he known of one in the service of colleagues.

In conclusion permit me to epitomize the following conclusions:

I. At least 90 to 95 per cent. of all tumors of the breast are malignant and no possible intelligence can determine which of the remaining 10 per cent. will remain benign.

II. There is no known cure for any tumor of the breast, benign or malignant, except through surgical removal.

III. From 25 to 50 per cent. of cases of breast cancer are permanently cured by radical surgical removal. With early diagnosis this percentage could be raised to 80 per cent.

IV. Every tumor of the breast, therefore, should be considered malignant and treated as such at the very first moment of its detection, unless incision has proven it benign, in which instance local excision should at least be insisted upon.

V. To trifle with tumors of the breast is, therefore, practically nothing short of criminal.

Radium Therapy in Gynecology.—Paul Petit says that the use of radium in the treatment of cancer of the breast is only justifiable when operation is impossible. Its greatest utility is for the purpose of preventing recurrence in the cicatrix. The rays have beneficial effects on all kinds of inflammatory processes, its effect being analgesic, decongestive, and resolutive. It may be used in a tube placed within the uterine canal for metritis or cancer. In the vagina it is used for cancer and for perimetritis. On the vulvar orifice it is useful for leucoplasia, cancer, pruritus, vaginismus, and dermatoses. On the adominal wall it is useful for localized peritonitis.—*La Gynécologie.*

A SUPPLEMENTAL REPORT ON THE OPERATIVE TREATMENT OF GONORRHEAL EPIDIDYMITIS.*

By FRANCIS R. HAGNER, M.D.,

WASHINGTON, D. C.

PROFESSOR OF GENITOURINARY SURGERY, GEORGE WASHINGTON UNIVERSITY. ATTENDING GENITOURINARY SURGEON, GARFIELD MEMORIAL HOSPITAL.

This supplemental report† of 12 new cases of the operative procedure in gonorrheal epididymitis is presented with the hope of obtaining a fuller discussion, especially from the members who have employed this surgical procedure since the presentation of this subject last year. The series of cases now reported permit me to answer in greater detail questions which then arose as to whether there were organisms to be found in acute gonorrheal epididymitis other than the gonococci.

Bacteriology.—Careful bacteriological examinations have been made on all the later cases. In the 21 cases reported last year either no organisms were present, or, if present, the gonococci alone were noted. In this series of 12 cases, gonococci were present in the epididymis in five cases. In six of them no organisms could be demonstrated in culture or cover slips; in one case a diplococcus was present morphologically like the gonococcus decolorizing by Gram's method, but growing luxuriantly on ordinary media. Dr. Wilkinson, assistant pathologist at Garfield Hospital, thought this organism was some contamination. In the 33 cases reported by me no organisms other than the gonococcus have ever been demonstrated. This fact is rather interesting, as I have never been able to secure any bacteriological data relating to gonorrheal epididymitis.

Fluid in the Tunica Vaginalis.—In cases 5 and 9 of this series a condition was observed in the tunica vaginalis which was not present in the other cases. In all the other cases there was fluid present in the tunica vaginalis. In case No. 5 the epididymitis was present seven days before operation and in case No. 9, three days. The condition in both of these cases was similar, namely, that no fluid was present and a great amount of fibrinous lymph was observed, resulting in an agglutination between the parietal

*Read before the American Association of Genito-Urinary Surgeons, May, 1909.

†The two previous papers on this subject appeared in the MEDICAL RECORD, December 1, 1906, and *Annals of Surgery*, December, 1908.

and visceral layers of the tunica vaginalis, and so firm was the adhesion that it was only with difficulty that these layers could be separated. Of the 21 cases reported last year, 13 came to operation on or before the seventh day of the disease, in all of which fluid was present in the tunica vaginalis. Of the 12 cases reported now, 10 were operated upon within seven days and in only two was there an absence of fluid.

Pus.—In 25 out of the 33 cases reported pus was present. In this connection case 12 is of particular interest because of the early development of suppuration. For ten days this patient had been under treatment for an acute gonorrheal prostatitis and had no symptoms of involvement of the scrotal contents. At 11 o'clock on the morning of December 16 he reported to me that during the previous two or three hours he had tenderness which he referred to the inguinal region. Palpation discovered no enlargement of the inguinal glands; however, there was tenderness of the cord near the ring, but there was neither pain, tenderness, induration, nor other sign of involvement of the epididymis. There was no change in his condition for twelve hours, when excruciating pain suddenly developed in the left testicle; this continued until 11 o'clock the next morning, when I saw him. At this time he had a well-marked epididymitis with marked swelling, the circumference being about 12 inches, and all of the characteristic signs of a most acute epididymitis—temperature 101°, leucocyte count of 18,000; there had been no chill. He was operated on three hours later—within fourteen hours of the first pain referred to the testicle.

At operation the tunica vaginalis contained two ounces of clear fluid, the globus minor was greatly thickened and covered with lymph; hemorrhagic areas were seen over the visceral layer of the epididymis; three distinct abscesses were found on puncture of the globus minor, one containing about half a dram of pus and the others about 20 drops each.

General Results. Pain.—Of the 34 cases operated on, with but one exception, which I mentioned last year, pain has been absolutely relieved by operation.

Induration.—I believe there is no question that the induration is much less following surgical treatment than after palliative treatment. In none of the cases have the hard and tender nodules, seen in cases treated palliatively, persisted after operation; although in a few of the cases, especially in those in

which the epididymitis has been of long standing, a general induration of the parts has persisted for some time.

Testicle.—In none of the cases have I been able to note any involvement of the testicle; the tension has not been increased, and no areas of induration were present.

Urethral Discharge.—I have had but one case that has had the recurrence of a profuse urethral discharge, such as is seen in the beginning convalescence in the cases not operated on. This occurred in case No. 12. By this I do not mean to say that patients do not have any urethral discharge after operation, as some have had a scant discharge due to inflammation of the urethra or its adnexa.

Recurrence.—I have had but one recurrence after operation; this was in a case I was invited to operate on by Dr. Tilden Brown at Bellevue Hospital. This was a very mild case, and not one I would have operated on from choice. There was no pus present and only very slight involvement of the globus minor. The patient made a good recovery, but returned in two weeks suffering from a recurrence on the same side.

There has been but one case with a double epididymitis; this is a recent case, and although the induration has almost entirely disappeared, no spermatozoa have been noted yet in the secretion; but one examination has been made. I am still hopeful that after complete resolution we shall find spermatozoa present.

Epididymotomy shortens the duration of the disease (the average period of confinement in my last series was about four days); it relieves pain immediately, convalescence is rapid; my results justify the conviction that the operation has a place in surgery.

1725 N Street.

A URINARY PROTEIN RESEMBLING BENCE-JONES ALBUMOSE, WITH CLINICAL HISTORY AND POST-MORTEM FINDINGS.

By J. E. DALE, M.D.,

FORT COLLINS, COLO.

Male, 27 years of age, married four years, bookkeeper, moderate drinker, denies syphilis, father dead, mother said to be consumptive. In good health up to December, 1907, when he was taken sick with what was said to be typhoid fever, this was on the strength of a Widal test by a competent pathologist. He was living in Kansas City at this time. He was taken to a hospital, where he remained for one week. There may have been some doubt as to the diagnosis, as he was seen by a number of physicians during this time. Tubercle bacilli were found in the sputum, and albumin in the urine. At the end of one week he was taken from the hospital on a stretcher and sent to Colorado. He survived the trip, and on reaching Denver was placed in the charge of a physician who put him on the usual milk, eggs, and rest-in-bed treatment for tuberculosis. After about three months his temperature became normal, his cough disappeared, and his weight came up almost to normal.

By September, 1908, he considered himself well enough to resume work, and came to Fort Collins, where he had secured a position. After three days he was forced to give it up on account of his eyesight, which he found to be very bad, though he had never had any trouble of this kind before. This trouble either grew better after a time or was less noticeable because the eyes were less used. No examination of the eyes was made.

In December he developed a troublesome diarrhea. Dr. Brinkman, at that time located in Fort Collins but now of Denver, was called, and

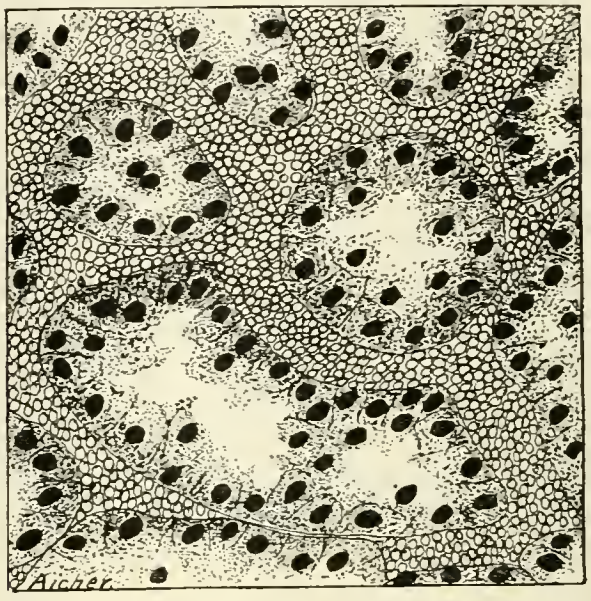

Fig. 1.—Section showing congestion and albuminoid degeneration.

had charge of the case for about six weeks, or until his removal. The writer was called for the first time on January 7, 1909, and found the patient very weak, moderately emaciated, voice hoarse, quite deaf, purulent discharge from the right ear, temperature slightly subnormal in the morning, but never above normal at any time in the twenty-four hours. The diarrhea was still persistent; stools fluid, grayish, bad odor, no occult blood or solid matter. Blood count was not made; hemoglobin was 90 per cent.

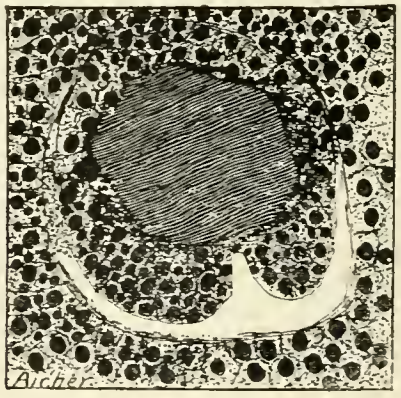

Fig. 2.—Inflammation and amyloid degeneration. Glomerulus.

On inspection, the left side of the chest was found somewhat flattened, the intercostal spaces retracted, and a very distinct, visible, cardiac impulse in the third, fourth, and fifth intercostal spaces immediately to the left of the sternum. The apex of the right lung was dull on percussion, the upper portion of the left side dull, the lower portion hyperresonant. There were moist râles on the right side; the breath sounds were faint or absent on the left side. The heart sounds were normal. Tubercle bacilli were found in the sputum. The ophthalmic tuberculin test was negative.

Urine: Amount for 24 hours 500 c.c., cloudy, color brownish red (No. 7 Vogel's scale), reaction acid, specific gravity 1.030, chlorides, fraction of one per cent. Microscopic examination gave numerous granular and few broad hyalin casts, blood, pus, and epithelial elements. Serum albumin was present in small amount, and another protein giving the following reactions:

(1) Precipitates with cold nitric acid, precipitate dissolves in greater part on heating, partly returns on cooling.

(2) Acidified with acetic acid, no precipitate.

(3) Saturated with sodium chloride in neutral solution, no precipitate.

(4) Acidified with acetic acid and saturated with sodium chloride, gave a copious white precipitate.

(5) Rendered strongly alkaline with sodium hydrate, upper portion in test tube, boiled and lead acetate solution added drop by drop, gave a very prompt and positive black precipitate (Boston's reaction).

(6) Saturated with sodium chloride and acidified with acetic acid and filtered, the filtrate was negative to 5, but gave a positive reaction for

Fig. 3.—Albuminoid degeneration and disintegration. Transverse section of tubules.

serum-albumin (a trace). Precipitate from above (6), dissolved in sodium hydrate solution, was positive with 5.

(7) Urine heated on water bath without either acid or alkali being added, faint coagulation began at 53° C. The coagulum was well marked at 55° C., but continued to increase to slightly above 60° C. Filtered after every 10 degrees rise in temperature the filtrate gave a faint reaction with 5, at 60° C., 70°., and 80° C., increasing slightly after 90° C., and after boiling, showing that a portion was being redissolved. Heated after saturation with sodium chloride the result was the same. Heated after acidifying with even a trace of acetic acid no precipitate was obtained before 80° to 85° C., the coagulum becoming flocculent and tough about 95° C.

(8) When a precipitate was caused to appear by heat in a neutral or unmodified specimen (the temperature not going above 80° C.), the addition of acetic acid promptly dissolved the coagulum.

(9) Heated to 55° C., filtered and the precipitate dissolved in 30 per cent sodium hydrate, the solution was positive with Millon's and biuret reactions (rose pink with the latter).

(10) Saturated with 95 per cent alcohol, filtered, precipitate washed with hot alcohol, then dissolved in boiling water, cooled, acidified with HCl and allowed to stand for some hours, then filtered, and the filtrate saturated with ammonium, and the resulting precipitate washed with the same until the wash water was negative to biuret test, precipitate then dissolved in dilute acetic acid, the resulting solution, gave reactions the same as the original urine. The precipitation with 95 per cent alcohol was not complete, the washings giving a precipitate with acetic acid and sodium chloride as well as the one with lead acetate, these reactions were faint but constant in all the hot alcohol washings.

(11) Saturation with neutral ammonium sulphate, precipitated all proteins.

(12) Nitric acid added drop by drop to urine heated in upper part caused a precipitate in the track of the drops, that, white at first, tended to become yellow on standing or with heat. No pinkish tinge was noted.

The patient never complained at any time of pain in any of the bones.

Under irrigation of the colon with physiological salt solution and a liberal diet the diarrhea disappeared, but the kidney conditions remained constant up to the time of his death, which occurred somewhat suddenly on January 25, 1909. The patient was feeling as well as usual up to 5 or 6 hours before death, when he suddenly began to complain of dyspnea, gradually growing worse. I saw him about 8 A. M. Respirations were 36 per minute, labored, pulse 95, soft, temperature 98.6°. By 11 A. M. the temperature was 99.3°, respirations and pulse both slightly quickened, moderate cyanosis. He died at noon, after being unconscious for about 15 minutes

Autopsy: Right lung, miliary tuberculosis, apex consolidated, no cavities. Left side, upper portion of lung almost completely consolidated, lower lobe hard and fibrous, almost unrecognizable macroscopically. The entire left lung drawn up and back. In the fibrous lower lobe, in the part in direct contact with the heart was a cavity, oval in shape, about 7 by 4 by 2 centimeters. The heart was less than normal in size, and drawn up and to the right, no dilitation or valvular lesion could be found. In the right side of the heart was a very perfect, firm, nodular, antimortem clot (described in the pathologist's report). No lesion of the blood vessels. In the abdominal cavity, liver, spleen, and pancreas were normal, there was no evidence of tuberculosis. Condition of kidneys is given in the pathologist's report. There was no evidence of change in any of the long bones (multiple myeloma). The heart, kidneys, and portions of the lungs were submitted to Dr. B. F. Kaupp, Pathologist at the Colorado State Agricultural College, who kindly examined them, and whose report is attached.

Attention is called to the fact that, with the exception of the solubility of the low temperature coagulum in acetic acid, and the precipitation with ammonia, the reactions of this substance (which the writer believes to be histon) apply to Bence-Jones albumose.

The following is the report of the microscopic findings of the specimens by Dr. B. F. Kaupp, Pathologist, Colorado Agricultural College:

"Heart: The right side contained an antemortem clot which presented some peculiar characteristics.

A pedicle like portion was adherant to the inner surface of the auricular appendage, extended down through the auriculo-ventricular opening forming a mass under the valves as large as a man's thumb. A microscopic examination of the pinkish mass showed it to be an ante-mortem clot. Lung: The sectioned surface (after passing specimen through the Keiserling fluid) presented for the major portion miliary tubercles, other portions showed areas up to one-half inch in diameter of cheesy degeneration.

Kidneys: The most interesting study is in the kidneys. Perhaps slightly larger than normal, they presented a grayish appearance. A microscopic study showed a parenchymatous inflammation. The following is a detailed description: Fig. 1 shows an area much congested and the cuboidal cells in a state of albuminoid degeneration. All areas did not show this congested condition. Fig. 2 shows a glomerulus in a state of inflammation and amyloid degeneration. This same condition existed in a major portion of the glomeruli. This condition is described as following long continued cases of tuberculosis as in this patient. Fig. 3 shows an area which is neither congested nor inflamed, but in a state of abuminoid degeneration. Some of the cells are disintegrating and desquamating."

Case II.—Bence-Jones Albumosuria. The following history is taken from notes made in 1904. Owing to the unfortunate failure to obtain an autopsy the case was not considered complete and was never reported. However, the comparative study of the chemical reactions obtained in these two cases will perhaps warrant its presentation at this late date and in an incomplete form. Male, laborer, age 19, unmarried, temperate habits, no diseases except measles when a child, and mild attack of smallpox in 1902. Home surroundings poor. Has worked for several years for various ditch contractors, living for the most of the time in tents. Work is hard, food is usually good, but water is bad as a rule. January 24, 1904, a specimen of urine was left at my office for examination, with the statement that it was from a case of "Bright's disease." This specimen was loaded with an albumose, with loosely combined sulphur.

Patient was seen the next day and the following history elicited: Five weeks before it was noticed that face and eyelids were swelling, a general anasarca developed and the patient became bedfast. Voice hoarse; urine scanty (reaction, specific gravity, total for 24 hours, etc., not noted, nor was the urine examined for albumin). A diagnosis of acute nephritis was made by the attenting physician, and the patient placed upon a milk diet, hot baths daily, and digitalis. The amount of urine was increased under this treatment, but little other improvement was noted, and he passed through the hands of several physicians during the next few weeks.

When, in company with the then attending physician, he was seen by the writer, the following conditions in addition to those already mentioned were noted: The mind was clear, vision and hearing normal, voice best described as husky and monotonous. A laryngoscopic examination showed the vocal cords slightly edematous with inability to approximate them. An area of cardiac dullness extended some distance to the right of the apex beat, there were no heart murmurs. There was a moderate bilateral pulmonary edema. There was well-marked tenderness over the inner aspect of the tibia on both sides, slightly more on the right.

Conditions remained unchanged up to about February 16, when he developed a troublesome cough. On February 18 he expectorated a quantity of bloody mucus and became very dyspneic throughout the day. The next day he complained for the first time of pain. This was in the region of the heart and apparently very severe, lasting about half an hour. These attacks recurred several times in the twenty-four hours until death. During the last three or four days he complained of constant and increasing chest pains that he described as "aching of the ribs." Several of the ribs became tender on pressure, particularly over sternal ends. The death of the patient occurred on February 25th. No autopsy was obtained by the attending physician.

Urine: Average amount for 24 hours, 1000 CC., specific gravity 1009, turbid, color reddish brown, reaction acid. In several of the specimens fibrin was present in considerable amount. There were some epithelial elements and a gradually increasing amount of blood. No casts were found, although searched for with care both in freshly voided specimens and in twenty-four hour mixed urine. Serum albumin was present in considerable amount. An albumose was present, giving reactions Nos. 1, 2, 3, 4, 5, and 6, as noted in Case I. These numbers were positive and similar in both cases. When heated on a water bath with the addition of acetic acid coagulation took place at from 51° to 56° C., varying decidedly in different specimens.

In order to determine the cause of this difference, a quantitive estimation of the various normal constituents of the urine was undertaken, and it was found that the coagulation point seemed to be uninfluenced except by varying proportions of chlorides. In all specimens the chlorides were very much diminished, though never entirely absent. As the proportion of chlorides was increased (by the addition of NaCl) the point at which heat caused coagulation was lowered, acidifying with acetic acid increased this tendency slightly. Up to 60° C. the coagulum increased; when it was filtered at this point the filtrate remained clear to about 70° C., but above this temperature coagulation of albumin took place.

The coagulum with heat was insoluble with acetic acid (see reaction No. 8 in Case I, which is the reverse). Reaction No. 9 was the same as in Case I, with a deeper shade for the biuret test. Reaction No. 10 was not worked out in detail, but the insolubility in acetic acid would seem to eliminite Histon. Reaction No. 11 was positive. Reaction No. 12 gave pinkish tint to precipitate, yellowish on standing. Millon's and biuret were positive.

Through the kindness of Dr. L. Napoleon Boston of Philadelphia, reprints or abstracted reports of cases of Bence-Jones albumosuria from the original report to the time this case was being studied, were made available for the writer. Dr. Boston also kindly examined a specimen of this urine, and stated that it probably contained Bence-Jones albumose. It is with regret and for comparison only that this incomplete report is submitted, as careful pathological studies based on post-mortem findings are clearly requisite to practical results from a study of these cases.

MEDICAL RECORD.

THE REFORMATION OF FOOTBALL.

AT the close of the football season a review of the fatal accidents of this autumn demonstrates that the efforts at reformation and modification during the past few years have not been entirely successful. The elimination of the flying wedge in 1894, the restriction a few years later of the number of men to be allowed behind the line, and finally the increasing the requirements for keeping the ball from a five to a ten-yard gain, and the introduction of the forward pass and outside kick were all heralded as radical changes which would eliminate the dangers of football. Each of these restrictions seemed at first to be an improvement, as after each change the list of fatal and serious accidents fell, but fell only to rise again in succeeding years as coaches and players learned new methods of utilizing or avoiding the new rules. The ten-yard limit was to make mass plays unprofitable and thus to promote a more open game. What this has accomplished, at least from the viewpoint of the spectator, has been to make the mass play even more strenuous than before, the increased vigor demanded by the increased need, and thus to make the danger of injury, and especially of fracture of the vertebra, even more imminent. The recent reforms have surely failed, and, especially moved by the prominence of some of the victims this year, the general public seems to feel more strongly than ever that if the game is to be continued some radical changes must be made.

It is not within the province of this journal to express the popular lay opinions or to dictate to the athletic committees as to the technical changes to be made in the rules of a sport, but one suggestion has appeared from several sources which deserves medical comment. This is the proposition to adopt a rule to enable the referee to order off the field any man whom he deems to be physically incompetent or, as one writer suggests, to have a special medical referee for that purpose. The latter alternative is possibly too extreme and too liable to be used by the enemies of the game ever to be adopted. The first suggestion, however, of the referee ordering off "groggy" men, is certainly excellent. As long as the present system of secret signals is continued mass plays in one form or another will be carried out. When the entire team knows which particular opponent has been selected for the target, as many men as possible will concentrate their power on that one player. If secret signaling is abandoned, American football will lose its most striking characteristic.

A young, strong man, with what help he receives from his fellows, if in good physical condition and in perfect control of his faculties, can be expected to withstand the onslaught of a line plunge and come through uninjured. When, however, he is exhausted, in pain, or dazed, the situation is different. It was discovered by a careful self-analysis by the Harvard team a few years ago that a player to receive a serious injury was almost invariably either exhausted or in some other way abnormal. In an ordinary fall a man, for protection, should relax his muscles. In football, however, with the continued grinding force of the mass play, every muscle must be kept tense, the head, arms, and legs must be held rigidly in the proper position, and he who relaxes and allows himself to be twisted or have his head forced backward is in a precarious position, indeed. This was learned at Harvard, and the early withdrawal of the exhausted or slightly injured man and the substitution of another is practised. Where, however, good substitutes are few, the coach naturally is not inclined to withdraw a star player, and he may be allowed to remain too long in the game with the result that, as occurred at West Point, after a comparatively slight injury, he continued to play and serious consequences followed. In such cases the referee should be privileged and in duty bound to order off the field any man who in his opinion is physically or mentally not under perfect self-control.

It is not to be expected that the adoption of this rule alone will make football devoid of accidents or that such a minor change will by any means satisfy the opponents of the game. It does, however seem, from the experience of the past season, to be a suggestion distinctly worthy of consideration, as a possible means of at least reducing the liability to such a tragedy as a fracture of the vertebral column.

THE RIGHT THING IN THE WRONG PLACE.

THE citizens and winter residents of Lakewood, N. J., are engaged in an earnest effort to defeat the projected establishment in that resort of a sanatorium for the prevention of tuberculosis in children. They fear, and with reason, that the presence of an institution of that kind within the town limits will change the character of the resort and that the successful establishment of one sanatorium will be followed by others, to the detriment of the place as a winter residence and as a haven for convalescents and nervous invalids. There is, of course, no danger to any person in Lakewood from the presence of four hundred delicate boys and girls, the children of tuberculous parents and themselves in the "pretuberculous stage," whatever that may mean, or actually harboring the seeds of the disease, but this truth is not yet fully appreciated by the laity. The man in the street attends a tuberculosis exhibit, sees the pictures and models, and reads the warning

signs, all intended to impress upon his mind the necessity of caution on the part of the sick, lest by carelessness they infect others. The first lesson he learns is that the tuberculous subject is a menace to the community unless the utmost care is observed in his spitting, in his eating, in his coughing, even in his talking. He is told also that, if the tuberculous subject is properly instructed and acts upon the knowledge that he is a focus of infection, taking the most minute precautions in the disposal of his sputa and in catching the spray from his mouth in coughing and talking, there is no danger to others in his presence in the community. But this lesson is not so impressively nor so graphically taught as the other. Moreover, he learns that the safety of the well man depends upon the caution of the sick one. The latter is a man with a lighted cigar in a powder magazine. He is told not to flick the ashes, and maybe, probably indeed, he will not, but the average person naturally prefers, so long as he is in the powder magazine, that the man with the cigar should stay outside, or if he is already inside, the other man would rather keep away. That is the lay feeling in the matter of tuberculosis, and it will take a long campaign of education before this fear can be eradicated. Medical men know that the safest place for those predisposed to tuberculosis is in the neighborhood of a well conducted sanatorium, but the laity cannot be blamed if they are slow in learning this lesson as a corollary to the first one taught, which is that the careless subject of tuberculosis is a danger to the community.

Sanatoria for the tuberculous are necessary, and their establishment must be aided by the law, as in this State, if communities are not sufficiently enlightened to permit it otherwise. But those who establish the sanatoria should proceed tactfully and with an endeavor to minimize the antagonism of their neighbors. The Loomis Sanatorium is a model in this respect. It is said to be at Liberty, but it is far from the town, it even has a separate post office, and no one in the place need ever, except on his own volition, come within miles of it. The proposed sanatorium at Lakewood is very different. It is close to the town, in the town in fact. At present it is in what is called the Cleveland cottage, so named because President Cleveland once occupied it, but it is proposed, it is so reported, to utilize the Lakewood Hotel and fill it with four hundred children predisposed to tuberculosis. It is euphemistically and cacophonously called a "preventorium," and not a sanatorium, but the public will regard that as a distinction without a difference. Those who have the project in hand have been offered free of cost a tract of many acres of forest land in a convenient location, close to the railroad, a few miles below Lakewood, and if they are wise and are actuated by a single desire to benefit their charges, they will accept it, and free this resort from the stigma which the presence of a sanatorium, unreasonably, but none the less surely, would put upon it in the mind of the public. If the laity is to be educated up to tolerance of tuberculosis sanatoria, or "preventoria," the educators should refrain from such a tactless forcing of an object lesson upon a community where the presence of their institution would inflict a serious pecuniary loss and possibly ruin what is now deservedly the most popular winter health resort within commuting distance of New York.

WOMEN IN MEDICINE.

James J. Walsh contributes an interesting paper under this title to the third volume of the *International Clinics* (Nineteenth Series) which has recently appeared. We are so apt to assume that the entrance of women into professional life is such a late event that the title suggests a study of the recent growth of medical education among women that dates from the end of the last century. Walsh, however, tells of far-away times when medical education was at no lower level than at present so far as qualifications for practice are concerned, namely seven centuries ago. In Southern Italy and Sicily at that time the student was obliged to spend three preliminary years at the University, followed by four years at the Medical School of the University and a fifth year as an apprentice to a physician, and then only was granted the right to practise.

It was at that time that women were active in medicine, not in time of decadence, therefore, but when the profession was guarded by judicious requirements for special work and ability. At the University of Salerno the department of the diseases of women was under the direction of a woman, and her successors were likewise women. Trotula, a noted gynecologist; Abella, who wrote on melanchily; Mercuriade, who was a surgeon and wrote a book on ointments and the care of wounds; finally Rebecca Guarana, who wrote a book on fevers—these are the few names from among the *medicæ salernitæ* that have come down to us, and the mere enumeration of their activities in the various fields of medicine shows how high they must have stood in professional knowledge and efficiency. One Italian woman, Alessandra Giliani, took up anatomy as a specialty and originated the practice of filling the veins and arteries with colored material and then varnishing the specimens for preservation. She was a prosector for Mondino, and, quotes Walsh, "she would cleanse most skillfully the smallest vein, the arteries, all ramifications of the vessels, without lacerating or dividing them; and to prepare them for demonstration she would fill them with various colored liquids which, after having been driven into the vessels, would harden without destroying the vessels. Again she would paint these same vessels so naturally that, added to the wonderful explanations and teachings of the master, they brought him great fame and credit." This authentic passage from an old chronicle shows that most modern methods are little if at all in advance of the technique elaborated by the women physicians of seven centuries ago. It is only the subsequent centuries of ignorance and lack of all interest and reverence for the study of natural science that could have led to the total loss of the knowledge of the art and science of medicine gained by the men and women of the earlier times.

Lack of space forbids us to delve further into the

interesting data given by Walsh. His chief aim seems to be to show that association of women with men in the art and practice of medicine has always resulted in the benefit of mankind and of medicine in general.

A New Posture in Obstetrics.

There is probably no branch of medicine in which the familiar saying that "fools rush in where angels fear to tread" applies as it does in obstetrics, particularly when the "fool" is armed with a new pair of Simpson forceps. The introduction of forceps into midwifry was certainly a great advance in that science, and their use when actually indicated is a great boon to the woman in labor. It is, however, a good rule never to apply instruments while there is a reasonable hope of a spontaneous delivery, and the condition of the mother and child is good. When the head is low down, as long as there is any advance, be it ever so slight, it is far safer to allow nature to take its course. There are, however, certain ways in which nature may be aided without in any way adding to the danger to the patient, one of the most important of which is posture. In the *Deutsche medizinische Wochenschrift* for October 28, 1909, Max Samuel of Cologne offers a suggestion as to posture which he believes aids greatly in hastening the later stage of labor, when the head has passed the pelvic brim, and the inferior strait is causing the dystocia. Drawing an analogy from the Walcher position, in which by hanging the thighs over the edge of the bed or table, and thus hyperextending the hips, the diameter of the pelvic inlet is increased at the expense of the outlet, thus enabling the head more easily to engage, the author argues that, when the head has once passed this point and the pelvic outlet is causing the trouble, the opposite posture, flexion of the thighs, will increase the outlet at the expense of the inlet. He therefore advocates in all cases where there is any delay, after the head has reached the floor of the pelvis, that the thighs be flexed and the legs held in the patient's hands, the knees also being flexed. By this process Samuel says that the pelvic outlet is widened, the woman is better able to use her pains, and that the pains themselves are less agonizing. He has made use of the posture in a large number of cases, and believes it to be of considerable value in hastening and easing labor and in preventing the necessity of applying forceps to the head in the outlet. If such a simple procedure really does save the necessity of applying forceps, with their ever-present danger to mother and child, it may prove a valuable addition to the armamentarium of the conservative obstetrician.

Fulguration for Cancer.

Like so many proposed cures for cancer, fulguration has given disappointing results so far as a cure without surgical interference is concerned. What is really gained by the use of high frequency currents after the method of Keating-Hart is a very great stimulation of the tissues, and a rapid cicatrization of wounds, no matter how large their extent. Thus it is possible by removing the cancerous mass, without making a clean sweep of all possible infected tissues, to get a cure by applying the fulguration method to all the uncovered and surrounding tissues. The cells that are involved which are left behind lose their malignant power. Large wounds that could not be cicatrized in any other way will heal quickly, permanently, and without much scarring, the cicatrical tissues being soft and pliable, instead of hard and contracted. In cases that are rated as inoperable this method is of the greatest value, permitting something to be done to prevent the spread of the malignant process. In a series of articles by H. Duret and René Desplats in the *Journal des Sciences Médicales de Lille*, for August and September, 1909, these advantages are thoroughly discussed. Cases are reported in which vast masses of cancer, after removal, were prevented from recurring and the surfaces cicatrized. Such cases would be absolutely hopeless under any other method of treatment, and surgery gives no hope of even a prolongation of life. The only bad results obtained are due to neglect of asepsis and the use of too strong applications of the current. The results are not so good in cancers of the mucous surfaces as in cancers of the skin. Cancers of the breast have done well in the experience of the authors. The best results have come from cancers which had largely invaded the connective tissues. An element in the cure is the marked lymphorrhea, the result of the removal of lymphatic engorgement, which assists in carrying off toxic materials resulting from rapid tissue changes.

News of the Week.

The Report of the Secretary of Agriculture, just published, contains a number of items of considerable medical interest. The outbreak of foot-and-mouth disease caused a considerable reduction in the exportation of cattle and sheep. Export inspections numbered 397,925, including reinspections of 227,255 animals for export from the United States. During the year 473 inspections of vessels carrying live stock were made. In stamping out this disease 3,636 animals were slaughtered, the value of which was $90,033.18. The amount expended for the eradication of the disease was kept within the special appropriation of $300,000. Continued progress has been made in the extermination of ticks that spread the infection of Texas fever among cattle in the South. During the year upward of 13,544 square miles were released from quarantine because of its having been freed from ticks. The freed areas were in the States of Virginia, North Carolina, Tennessee, Arkansas, Oklahoma, and California. The Department made a great forward movement in enforcing the food and drugs act. It now has branch laboratories for the examination of samples at 21 of the leading commercial centers, about one-half of these being seaport cities. Samples of foods and drugs imported from foreign countries are taken by agents of the Treasury Department. Inspectors of the Bureau of Chemistry collect samples of domestic products and inspect factories. The number of factories inspected during the year was 1,300, and the number of samples of domestic products taken was 15,000. Nearly 10,000 of these were examined in the laboratories, and about 2,000 were forwarded to the Department for reexamination. Of the imported products more than 8,000 samples were taken; 2,500 of these were sent to Washington for reexamination. Some flagrant violations of the law have occurred and prosecution of the violators has been vigorous. The Department Solicitor has prepared and reported to

the Attorney-General for prosecution 494 cases, and of those tried but two were lost. Convictions and fines aggregating over $2,000 were secured in 85 cases; and in 98 cases decrees of condemnation and forfeiture were issued covering many tons of food and drugs. As a result of these operations, misbranded and adulterated products are rapidly disappearing from interstate commerce. By careful inspection of foods and drugs imported from foreign countries, and a vigorous enforcement of the law, marked improvement in the character of the imports has been secured, and very few fraudulent or misbranded articles are now offered for entry. Since the passage of the Food and Drugs Act the "prescription scheme" has arisen. Under this plan of selling proprietary medicines, a prescription is sent through the mails. The prescription will contain several well-known medicinal agents, but also a coined name of some unknown product. To fill the prescription the recipient must purchase the agent sold under the coined name. Analyses of these products have shown that they usually consist of the cheapest and commonest of ingredients, though advertised as panaceas for various diseases. Such remedies are plainly fraudulent, since they have no curative properties for the diseases for which they are recommended. It has been discovered that many mosquitos are sewer-bred, and that malaria-bearing mosquitos in dry summers will breed in the sewer traps, making it extremely important that all sewer traps be treated with kerosene. An investigation of the effects of certain drugs commonly used in headache remedies of the present day, showed that the indiscriminate use of remedies containing these drugs without the advice of a physician frequently produces poisoning, a drug habit, or, in some cases, death.

Prize Offered for Tuberculosis Cure.—A person, whose name has not been made public, has offered a prize of $100,000 for the discovery of an absolute cure for tuberculosis. Yale University is the custodian of this prize, and the physicians attached to the Yale Medical School are to act as trustees. The trustees have invited many well-known physicians to become members of an advisory board whose duty it will be to pass on the merits of cures submitted. Among the physicians selected as members of this board are Dr. E. L. Trudeau of Saranac Lake, N. Y., Dr. Simon Flexner of the Rockefeller Institute, Dr. William H. Welsh of Johns Hopkins University, Baltimore, Dr. Lawrence F. Flick of Philadelphia, and Dr. Herman Biggs, chief medical officer of the Department of Health in this city. The donor places few restrictions on his gift and it is open to any scientist or physician the world over. The money will be held in trust, it is understood, and the interest from it will go toward investigating any cures the trustees or members of the advisory board hear of but that are not submitted to them for examination. The advisory board plans to hold four meetings a year, and will hold others if the cures or alleged cures that are submitted warrant it. One of the duties of the advisory board will be the exposure of "fake" consumption cures which may come to their notice. So that the advisory board and the trustees will not be bothered with bogus remedies, one of the restrictions in the deed of gift is that the remedy must have been in use for five years and must be backed up by reliable testimonials that it has resulted in cures.

Opposition to a "Preventorium" at Lakewood.—A committee of citizens of Lakewood, N. J., recently held a meeting to protest against the establishment of a Preventorium in the city. The superintendent of the institution was arrested on the charge of bringing dependent children into the State without permission of the State Commissioner of Charities and was held in $2,500 bail. Appeal was made by the backers of the institution to Governor Fort on the ground that the children were not diseased but merely run down, to which the Governor has responded that the law to prevent the importation of tuberculous children into the State would be enforced.

Smallpox in Mexico.—A dispatch from Torreon, Mexico, states that there is a severe epidemic of variola among the miners of the Santa Barbara mine near there. The mine physician has eighty cases of the disease under his care, several of the patients being Americans.

Deportation of Alien Insane.—According to the annual report to the State Commission in Lunacy by its Board of Deportation, 489 insane and defective aliens were deported from New York during the fiscal year just ended. The commission estimates that the State saved from these deportations about $978,000. During the year there was an increase in the total number of immigrants passing through Ellis Island of 287,276, and the work of the board was increased 50 per cent. With the aid of the Lunacy Commission the board obtained the removal to other States of 165 additional insane patients who had found temporary domicile in the State hospitals.

Investigation of Christian Science Death.—A coroner's inquest has been investigating recently in Winsted, Conn., the death of a man, thirty-seven years of age, who died of a pulmonary trouble after an illness of one month. During that period he was visited three times by a Christian Science healer from Hartford, beyond which he had no treatment except that of the absent kind.

The Cuban Secretary of Health and Charities, Dr. Matias Duque, recently resigned and has been succeeded by Dr. Manuel Varona Suárez.

A Postgraduate Course in Tropical Medicine is announced by the Oakland (California) College of Medicine, to be given from January to March, 1910, under the direction of Dr. Creighton Wellman. It is intended that the course shall be as practical as possible, the students preparing and examining their own specimens. Especial attention will be paid to tropical diseases already endemic in this country. The course begins January 3, 1910.

Candidates for Blood Transfusion.—In response to an advertisement inserted in two New York papers recently, offering a substantial reward to a young, healthy man willing to be a donor in a transfusion operation, sixty applicants appeared.

Medical Needs of New York.—The annual report of the Charities Organization Society of New York calls attention to the great need of more beds and more hospitals for tuberculosis patients. The report also instances a number of local needs for varying neighborhoods. In the Greenwich district it calls for "healthful, decent tenements at moderate prices"; in the Chelsea district, "better housing accommodations, and a day camp for consumptives in addition to a free milk depot for the

benefit of tuberculosis cases." The Riverside district, situated on the upper west side, with its center at 127th Street, the report states needs a good general hospital, a night dispensary, a day camp, and a night camp for tuberculosis patients.

New Hospital for Brooklyn.—Plans for the new Bradford Street Hospital in the East New York section of Brooklyn were filed recently in the Bureau of Buildings. The hospital will cover the entire block on Dumont street between Miller and Bradford streets and will have a capacity of a hundred beds. It will be five stories in height with an extension of two stories. The building will be in the early Italian Renaissance style and will be constructed with a granite base and red brick with terra-cotta trimmings above and will be fireproof throughout.

The Bayonne Hospital was dedicated recently. The building is in East Thirtieth street. It is of brick and three stories in height. It is well equipped and it cost about $60,000.

Uniform Medical Civil Service Examination.—Standard examinations for all places of physician in the classified service have been established by the National Civil Service Commission in place of the different standards set up by the various departments. The change is important in that it will enable an applicant, by passing one examination, to become eligible for appointment in any branch in which physicians are employed. This departure is in line with the policy of the commission of providing standard examinations for all places for which the duties are the same.

American Society of Sanitary and Moral Prophylaxis.—The next regular meeting of this society will be held at the Academy of Medicine, Thursday, December 9, at 8:30 P. M. The general subject for discussion will be: "Shall the State Require a Medical Certificate of Freedom from Transmissible Disease as a Condition of License?" Papers will be presented by H. M. Johnston-Wood, Charlotte Perkins Gilman, and L. Duncan Bulkley, M.D.

The Southern Surgical and Gynecological Association will hold its twenty-second annual meeting at the Hot Springs Hotel, Hot Springs, Va., December 14, 15, and 16, 1909. The president of the association is Dr. Stuart McGuire of Richmond, Va.; the secretary is Dr. W. D. Haggard of Nashville, Tenn., and the chairman of the committee of arrangements is Dr. Lewis C. Boscher of Richmond, Va.

The Southern Medical Association completed its third annual convention on November 11, 1909. The following officers were elected: *President*, Dr. W. W. Crawford of Hattiesville, Miss.; *Vice-presidents*, Dr. J. F. McInstry of Florida, Dr. W. S. Leathers of Mississippi, Dr. I. R. Snyder of Alabama, Dr. H. L. Harris of Georgia, Dr. George Dock of Louisiana, and Dr. Frank Jones of Tennessee; *Secretary-Treasurer*, Dr. Oscar Dowling of Shreveport, La. The convention of 1910 will be held at Nashville, Tenn., during November.

The Second District Medical Society of Iowa, at its annual meeting held at Davenport recently, voted to meet again next year in the same city. The following officers were elected: *President*, Dr. L. W. Littig of Iowa City; *Vice-Presidents*, Dr. E. H. King of Muscatine and Dr. G. F. Harkness of Davenport; *Secretary-Treasurer*, Dr. John V. Littig of Davenport.

The Hardin County (Ky.) Medical Society, meeting at Elizabethtown, November 12, 1909, elected the following officers for 1910: *President*, Dr. C. C. Carroll of White Mills; *Vice-president*, Dr. D. E. McClure of Sonora; *Secretary* and *Treasurer*, Dr. J. M. English.

The Des Moines County (Iowa) Medical Society, at its annual meeting, at Burlington, Iowa, recently elected officers as follows: *President*, Dr. Charles F. Frantz; *Vice-president*, Dr. Fred Koch; *Secretary*, Dr. Julia Donahue.

The Italian Medical Society of New York held its first annual dinner at the Hotel Astor recently. More than 400 members of the Italian colony and invited guests attended. Dr. Antonio Stella, president of the society, was toastmaster.

The Harvey Society.—The second lecture of the Harvey Society will be delivered by Dr. Otto Cohnheim of the University of Heidelberg on Saturday, December 4, at the New York Academy of Medicine, at 8:30 P. M. The subject of the lecture will be "The Influence of Sensory Impressions on Scientific Deductions." All physicians and others interested are cordially invited to attend.

The Clinical Society of the West-side German Dispensary and Hospital was organized November 24, 1909. The society is composed of the members of the staff and the faculty of the New York School of Clinical Medicine. The following officers were elected: Dr. Robert N. Disbrow, President; Dr. Leon F. Garrigues, Vice-president; Dr. D. L. Morrison, Secretary. The meetings will be held on the first Tuesday of each month.

Obituary Notes.—Dr. WILLIAM T. ATKINSON died at Philadelphia on November 23 at the age of 76 years. He was graduated from Jefferson Medical College in the class of 1853. He was at one time lecturer on obstetrics and diseases of children in that institution and subsequently he occupied a similar position in the Medico-Chirurgical College. He was for many years secretary of the Medical Society of Pennsylvania and also of the American Medical Association.

Dr. JOHN PIERRE FRISHMUTH died at Philadelphia on November 20 at the age of 41 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1890. He was at one time connected with the American Hospital for Diseases of the Stomach and he was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. JACOB QUICK died at Philadelphia on November 20 at the age of 84 years. He was graduated from Rutgers College in the class of 1847 and from the Medical Department of the University of Pennsylvania in the class of 1851. He enlisted in 1862 as surgeon in the 22d New Jersey Infantry Regiment and at the close of the war took up his residence in Trenton, N. J. He removed to Philadelphia in 1879.

Dr. I. NEWTON SNIVELY died at Philadelphia on November 23, following an operation for ulceration of the bowel, at the age of 45 years. He was graduated from Chambersburg Academy, from Gettysburg College in 1887 and from Bellevue Hospital Medical College in the class of 1889. He was for a time connected with the Medico-Chirurgical Hospital, and subsequently he became physician to the Samaritan Hospital and later Professor

of Materia Medica, Therapeutics, and Clinical Medicine in the Medical Department of Temple University and dean. He was a member of the Philadelphia County Medical Society, Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. Frank Bradford Sprague of Providence, R. I., died on November 17, 1909, aged 44 years. He was a graduate of the Medical Department of the University of Vermont in 1889. For the past fifteen years Dr. Sprague had confined himself to the diseases of the ear, nose, and throat, in which specialty he had attained a national reputation. He was aural surgeon to the Rhode Island Hospital and was a member of the Rhode Island Medical Society, the New York Academy of Medicine, the American Otological Society, the Medical Improvement Club of Providence, the American Laryngological, Rhinological, and Otological Society. He was a fellow of the Academy of Ophthalmology and Otolaryngology.

Dr. Esther H. Young of Minneapolis, Minn., died at the Asbury Hospital November 15, 1909, of carcinoma, aged 63 years. Her husband dying in 1891, she took up the study of medicine, graduated from the medical department of the University of Minnesota, in 1893, and became one of the best-known women physicians in the State.

Dr. James Wharton McLaughlin of Austin, Texas, died November 13, 1909, aged 69 years. A native of Ohio, Dr. McLaughlin was a Southern sympathizer and fought through the Civil War in the Confederate army, afterward settling in Texas and graduating from the Medical Department of Tulane University in 1867. From 1895 to 1907 he was Professor of Medicine in the University of Texas and since then has been a regent of the University. At various times Dr. McLaughlin has served as president of the Travis County Medical Society, the District Medical Society, and the Texas State Medical Association.

Dr. Samuel James Kelly of Fall River, Mass., died at his home November 15, 1909, aged 53 years. He was a graduate of the Ecole de Médecine et de Chirurgie in Montreal, in 1888, and was a member of the Fall River Medical Society.

Dr. Samuel Kahn of New York died at his home on November 26, 1909, of chronic nephritis, aged 55 years. He was a graduate of the New York University Medical College in 1877. Dr. Kahn was the founder, president, and attending physician of the German Poliklinik. He was a member of the German Medical Society and the Physicians' Mutual Aid Association.

Dr. Charles K. Cutter of Somerville, Mass., died suddenly on November 11, 1909, at his home, aged 59 years. He was a graduate of Tufts College in 1872 and of the Harvard Medical School in 1876.

Dr. Samuel Brightwell Smallwood of Long Island City died at the Post-Graduate Hospital November 27, 1909, aged 69 years. He was a graduate of the New York University in 1864, and was a member of the Queens-Nassau Medical Society and the New York State Medical Association

Dr. William Geoghan of New York died November 27, 1909, of heart disease, aged 55 years. He was a graduate of the Albany Medical School in 1874, and was a member of the Medical Society of the County of New York and the New York State Medical Association.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INFLUENCE OF MIND OVER BODY—PSYCHOSES—THERAPEUTICS OF SUGGESTION, HYPNOTISM, ETC.—SIR HENRY MORRIS, P.R.C.S., ON CHRISTIAN SCIENCE—KING'S BIRTHDAY—SURGEON-GENERAL EVATT ON HEALTH OF THE PEOPLE—OBITUARY.

London, November 12, 1909.

For a considerable time there has been a recrudescence of interest in certain phases of psychology—hypnotism, suggestion, mesmerism, etc. The subject was even brought before that august medical body, the Royal College of Physicians, in the Harverian Oration, on the 18th ult., as I mentioned in a former letter. The orator this year was Dr. Savage of Guy's, whose reputation on mental disease must be well known to you, but even he remarked that in treating of these subjects he felt "on dangerous ground," and knew that many of his colleagues would shake their heads and doubt the utility of considering them. But the advice of Harvey was to "follow truth without fear as to whither it may lead." So far as he had gone it seemed to him more than likely that the two opposing forces—experimental psychology and hypnotism—may after all unite on scientific advance. As to hypnotism, he said he began with doubt, passed into a stage of indifference, and has now reached the stage of hope.

Dr. Savage accurately diagnosed the mental attitude of a proportion of his distinguished audience, though many were inclined, after the facts he related, to give consideration to the subject in all its aspects, especially in the scientific direction. The general interest in such matters was considerably increased by this oration, and was further shown by a discussion on the 28th ult. at the Harverian Society. This was opened by Dr. Claye Shaw, emeritus lecturer on psychological medicine at St. Bartholomew's. Suggestion, he remarked, was the insinuation of a belief or impulse into the mind of a subject by any means, words, gestures, emphatic declarations, etc. But there was also the impulse of trust and submission required to make the incitement effective. It is no new thing; it was applied in early ages and at various times since. There are two schools; one holds there is a purely mental element, susceptible to influence by appeal to it as a separate primary agent; the other says mental conditions are inseparably associated with nerve states, and denies the existence of such entities as will and active attention. The modern school of psychology is absolutely materialistic, and insists that will, attention, etc., are results, not causes, but many who have insisted on this find themselves saying there is yet something to be explained, for "I will" goes beyond "I must." Psychologists tell us that voluntary action and attention can be split up into certain components, and depend chiefly on the strength of emotion; but we know nothing of the real nature of emotion or what nervous or visceral condition may or may not be concerned in making it strong or weak. By telling a person afraid of something that there is nothing to fear, and insisting so, we may change his emotion and perhaps his will and attention, but we do not so impose our will on his. Moreover, the change is gradual, whatever it may be. No doubt many of us use suggestion without noticing it. We rouse hope or inspire confidence by personality, arousing dormant tracts of thought. In presence of one mental state it is difficult to recognize the existing of opposite ones which are dormant. That a person feels depressed does not imply that the brain condition correlated with joy and contentment does not exist. It is only dormant or overshadowed, and here perhaps is the explanation of treatment by suggestion, raising it to a reasonable hypothesis. There is then no need for theatrical tricks, but a right-thinking man may possibly think some things will enforce his legitimate suggestion, say, silence, fixed gaze, passes, and so on. Putting aside the doings of quacks and clever amateurs, and regarding only the work of medical men who have systematically used suggestion alone, or in combination with hypnotism, Dr. Claye Shaw asked whether there was valid ground for using it as a therapeutic agent, and replied that, personally, he believed there was.

Dr. Milne Bramwell, following, referred to Elliotson and Braid, who both desired to determine the mental influence of drug-taking. Some men, like Gall and Andrew Clark, obtained great successes with the simplest remedies, and their personal influence might be to some extent the cause. Dr. Hack Tuke held that he could do with suggestion what he could not by drugs alone, and Benedict said

the effects attributed to magnets were really due to hypnotism. James Braid's earlier work was well known, but many were unaware that later he found simple suggestion as useful as hypnotism, and had left the testimony that not one in ten of those he cured had passed into a state resembling sleep.

Dr. Bramwell, continuing, mentioned some of his cases which had greatly benefited after suffering for years. He said suggestion would cure some who were quite disheartened and suicidal. Its best cases were of obsessions, and no one supposed a dread of enclosed space or a morbid fear of cats yielded to drugs. He had cured a man with an obsession that he must throw himself out of a window, and the patient had remained well and doing useful work. He could not explain these cures, and he certainly had no claim to any mysterious influence. But he was glad the subject was getting more attention, that a society to study it was formed, composed of medical men, and 80 had already joined.

Dr. Seymour Tuke, as an alienist, could not report encouragingly. Only cases sane except on one point, *i.e.* when the power of attention and concentration remained, were benefited. Suggestion was wonderfully effective in inebriety if the will was under some sort of control. Possibly a mental physician constantly in contact with patients might get into a sort of communion with them and so exercise a slow suggestive influence.

Dr. Lloyd Tuckey had employed suggestion for twenty years, and said dipsomania and other diseases which drugs could not touch were amenable to it. He had never known it to harm, and the profession ought to employ it in appropriate cases. When they were trained in psychotherapeutics patients would come to them instead of going to quacks.

Mr. Stephen Paget spoke about "Christian Science," which he has done much of late to expose. Dr. R. H. Cole said he studied the subject at Paris twenty years ago, and was much disappointed. Hypnotic suggestion might be powerful for either good or evil, and should be used only by specialists. It would cure dipsomania, but he had never seen it benefit insanity with fixed delusions.

Dr. J. F. Woods had treated 4,000 cases—some with remarkable results—and he enthusiastically supported suggestion. It was not necessary to induce hypnotic sleep. He usually put the patient in an armchair and told him to compose his thoughts and relax his muscles. Sometimes he might stroke the forehead or epigastrium, and when the patient seemed comfortable make suggestions of quiet, rest, warmth, etc. In some cases he would then leave the patient for half an hour, and on returning it was not uncommon to find him asleep.

Mr. Armit said a stranger had more influence over a patient than his familiar doctor. People talked of the will, of mind, and the subconscious mind, of which nothing was really known, but because a thing could not be explained was no reason for denying that it had influence. To stop the doings of outsiders the profession must use these remedies properly.

Dr. E. L. Ash said verbal suggestion was often scarcely enough. In addition, hypnotic sleep might suffice, but material treatment was better. Giving a placebo and telling the patient what to expect was suggestion of a half-hearted kind which many had resorted to. Surely it was better that suggestion should take its place as an ordinary adjunct to other therapeutic proceedings. To make a specialty of it was as unscientific as it was retrograde.

Two or three other speakers mentioned cases in general practice, and Dr. Shaw, replying admitted that the testimony brought forward in the debate satisfied him that suggestion and hypnotism were definitely useful remedies.

Last night Sir H. Morris, president of the Royal College of Surgeons, addressed the Medical Society of the Middlesex Hospital, on "Superstition and Research." He said the great advances made were due, in the words of John Donne, to "the sacred hunger of science." As to the kind of science he would say physical. That, searched for truth by the method of research; at present quackery was rife in Germany as "natural treatment," in this country and America as "Christian Science." This last ignored the reality of sickness and called for "spiritual force" to remove the idea of disease, saying actual disease had no real existence. Mrs. Eddy and her followers practically claimed to work miracles none the less by talking of the "annihilation of illusion." But their miracles differed from those of the New Testament by requiring faith in the patient instead of in the healer, by refusing physical means, and by inability to do what they were told could be done under the Christian dispensation and was done by the apostles. The only passage they quoted said they should lay their hand on the sick. How could they do so when they pretended to heal at a distance? Why did they disregard the other endowments mentioned in that text? Let them speak with new tongues, take up serpents, drink deadly things, and so show that imputations of manslaughter and deceit made against them are not merited. Our repugnance to their presumption was because they misled the credulous, the ignorant, and the helpless into supposing that miracles would be wrought at their instigation, and so persuade or even enforce their victims to refuse physical means of cure. As medical men we were not concerned with their muddling with metaphysics, but with their meddling with medicine to the injury of the sick through their cruel and fatal practice. It was in the interest of the suffering one should oppose false teaching about disease and sickness. Within the last few days, Sir Henry said, his hearers might have read Lord Curzon's letter on a pretended interview between a notoriously hysterical journalist and the spirit of an illustrious dead person, to which publicity had been given as a political maneuver on behalf of an unpopular budget. In the same period also the trial and verdict for £1000 damages against a hypnotist whose cures and indifference to the "cage of death" were vouched for by many credulous witnesses. He commended the judgment of the judge in that trial to their careful perusal.

The honors list of the King's birthday is rather disappointing in some quarters, for medicine proper seems quite neglected. But chemical science is noted in Sir Henry Roscoe, F.R.C., who becomes a Privy Councillor, and in Professor Tilden, F.R.S., who represents that science in relation to pharmacy, and receives a knighthood. Dr. J. A. Haran is an M.D. and M.A. and the M.O.H. of Mombasa, and gets the C.M.G. Mr. J. M. Moody, M.R.C.S., has been for twenty-five years superintendent of Cane Hill Asylum, and gets a knighthood. So does Dr. G. H. Pollard, who is a Doctor of Medicine and a barrister as well, but his promotion is due to his being an M.P. and a supporter of the government.

Surgeon-General G. J. H. Evatt gave an address on the "Health of the People" on the 8th, in which he declared the higher type of doctor took up the study of prevention rather than cure, and of this type the army offered the first examples. It was, he said, of extreme importance that the officer sent to inspect barracks should not be subordinated to the one in charge, and just so the civilian medical officer of health ought not to be under the dismissal power of the local authorities without power of appeal. He believed that the temperance question had been solved in the army by doubling the entire space and by providing libraries and recreation rooms, and so the same result might be attained by the civil community enforcing the same measures.

Mr. H. H. Clutton, Senior Surgeon to St. Thomas' Hospital, died on the 19th inst., after a long illness, aged fifty-nine. He was a member of the Council of the Royal College of Surgeons and representative of that body in the senate of the University of London. He was a Cambridge graduate M.A., M.B., and C.M. His career at St. Thomas', where he had also been a student, was one of success. His works on "Diseases of the Bones" and on the "Surgery of Deformities" will be known to you, as will his contributions to the treatises of surgery, the medical societies, and the journals. Yesterday the Council of the College of Surgeons passed an appreciative resolution of regret at the loss of their colleague.

Deputy Surgeon-General J. E. Scott (retired) has died in Dublin, aged eighty-five. He took the Dublin M.D. in 1854 and M.R.C.S., England, in 1846.

OUR PARIS LETTER

(From Our Regular Correspondent.)

FRENCH ASSOCIATION OF UROLOGY—URETERAL CALCULI—IONIZATION IN GONORRHEA—URETHRAL BULBITIS—OPERATIVE INDICATIONS IN GENITAL TUBERCULOSIS—PENETRATING WOUND OF THE RECTUM AND BLADDER—BILHARZIONIS OF THE BLADDER—CYSTOSCOPY BY DIRECT VISION.

PARIS, October 30, 1909.

At the opening session of the French Association of Urology, Jeanbrau of Montpellier presented a very complete study of the anatomopathology of calculus of the ureter. He indicated what were the functional symptoms showing the presence of calculus in the ureter, whether in the lumbar region, in the juxtavesical region, or finally in the pelvis. From the point of view of prognosis, every calculus pursued fatally its destruction of the kidney which had formed it; further, it prepared anuria for the time when the obliteration of the opposite ureter should take place. The diagnosis might be made by palpation of the abdomen,

vaginal touch, rectal touch, cystoscopy, and ureteral catheterism. The precise diagnosis should always be made by radiography, which should be systematically practised always, of the entire urinary apparatus. The best means of avoiding all radiographic errors consisted in making the radiograph after ureteral catheterism with a sound with metallic staff. From the point of view of therapeutics the extraction of ureteral calculus must be made systematically and more quickly than in calculus of the kidney. In periods of anuria we should attempt to catheterize the ureter last obstructed, and that maneuver might be followed by re-establishment of the flow of urine. From the operative point of view three methods allowed of the removal of ureteral calculi—extraction through the upper part of the ureter after nephrotomy or pyelotomy, extraction by the lower orifice after cystotomy, extraction of the calculus by incision of the ureter or ureterolithotomy. The last operation gave excellent results and a cure often resulted without a fistula when the surgeon had verified the permeability of the ureter below the calculus and incised the stricture if it existed.

Legueu drew attention to a special symptom which was met with in calculus of the ureter, the defensive contracture of the abdominal wall. This sign often showed the point at which to operate. Legueu observed an interesting case in which an extremely mobile calculus of the ureter, following the position of the sick man, passed from the termination of the ureter to the pelvis of the kidney. He operated on this patient by nephrotomy in inclined posture, to make the calculus descend to the region of the kidney, where it was removed. George Luys believed that from the diagnostic point of view, aside from radiography, a simple means of ascertaining the presence of the calculus in the ureter was to catheterize the ureter; by withdrawing with slight jerks the instrument the roughness characteristic of the condition might be felt. From the therapeutic point of view a surgical operation should only be performed when attempts at extraction by the natural passages had failed. Among these we must remember how easily the lower extremity of the ureter could be reached with the cystoscope for direct vision. The duct could be easily dilated and the maneuvers practised directly in its interior. Desnos succeeded in three cases, in the course of nephritic colic, in causing the immediate passage of the calculus by ureteral catheterism. When the calculus had been held for a long time in the ureter we might try to practise ureteral catheterism, but softly and with a small and extremely soft sound, for perforations of the ureter had occurred. Tedenat of Montpellier said the diagnosis of ureteral calculus had been rendered more precise by radiography. Some calculi caused no shadow; uric acid calculi and other forms in different lesions might give the impression of ureteral calculi; such were calcification of the ureters, glands, and ligaments. We must know how to control our radiographs by knowledge gained by ureteral catheterism and previous attacks of colic which had or had not ended in the expulsion of the stone. Arcelin of Lyons insisted on the radiographic shadows of the pelvic cavity. Aside from radiographic shadows due to the presence of ureteral calculi, there were other shadows similar in all points to these, due to opaque bodies situated outside of the urinary passages. Radiography alone did not permit us to distinguish urinary calculi from other bodies opaque to the *x*-rays. Among these some had a fixed, others a movable, position. By radiography associated with catheterism of the ureters, with a sound opaque to the *x*-rays, we might distinguish calculi of the ureters and make a precise diagnosis. Henry Mariger of Paris had studied ionization applied to the treatment of chronic ureteritis, and gave his conclusions from 29 cases, of which 11 had remained cured for from six to twenty-four months. Paul Hamonic of Paris spoke of ureteral bulbitis, which was an inflammation of the juxtaurethral bulbar curve. This form was extremely rare, and Hamonic had seen it only seven times in twenty-four years. Blenorrhagia was the most important etiological factor. When the infection was intense little fissures were produced in the mucous membrane of the ureter, which acted as doors of entry for the germs. Wounds made in the course of catheterism had the same effect. The essential symptoms were a painful swelling of the bulb, which took the form of a little club; resolution was the rule. Suppuration began with extremely painful dartings. The disease might end in gangrene and death by infection. The diagnosis was made from Cowperitis, which was lateral, while bulbitis was median. Panchet of Amiens had fixed the operative indications of genital tuberculosis in men. Genital tuberculosis in man should be treated by total extirpation of the spermatic passages, epididymis, vas deferens, vesicles, and prostate, whenever the lesions were limited to one side and there were not advanced lesions of the urinary apparatus or lungs. The operation had three steps—inguinal, for the dissection of the vas deferens as far as the bottom of the pelvis; scrotal, for the resection of the epididymis or castration; perineal, for the extirpation of the vesicles and excision of the diseased prostate. The cure was complete and the final results were very good. Drs. Duret and Lepoure of Lille presented a case of perforation of the rectum and bladder by a penetrating wound. Penetrating wounds of the rectum and bladder by impalement were rare and up to the present time their treatment had not been established in a satisfactory manner. The evolution of penetrating wounds of the rectum and bladder was spontaneously favorable. But we must foresee the complications of a secondary nature that change the prognosis. An early cystotomy might be indicated in an analogous case.

Ernst and R. W. Frank of Berlin had examined at St. Peter's Hospital, in London, two cases of bilharzia of the bladder by cystoscopy. The two patients were infected during military service in South Africa from drinking water. After cystic pains there appeared dragging and burning pains in the lumbar region. Hematuria then occurred, at first terminal, then frequent and most intense, so that general enfeeblement and anemia ensued. The eggs of the Distoma were found in the urine of both patients. Gauthier of Lyon gave the indications for cystoscopy by direct vision. The author had made use exclusively of the instrument of Luys. Basing his conclusions solely upon his personal observations, he gave the following indications: ablation of foreign bodies, biopsy of tumor, diagnosis of the cause of an abundant hematuria at the moment of examination, ureteral catheterism (a) when the ureteral orifices, on account of stricture, prolapsus, etc., or the ureters themselves attacked by inflammation and stricture, would not admit sounds passed by means of the prismatic cystoscope; (b) when blood or pus fell momentarily from the kidneys or a vesical lesion, tumor, or ulceration made turbid the water introduced into the bladder for cystoscopy by the prism; (c) when the vesical capacity was very much reduced below 20 cubic centimeters. The instrument of choice for certain operations within the bladder, the Luys cystoscope, for exploration of the bladder and catheterism of the ureters, should give place to the cystoscope with prism. Jeanbrau of Montpellier showed a cystoscopic view of a leek which had been introduced into the bladder by a man forty years of age. This leek was 24 centimeters in length and 11 millimeters in diameter. It was removed by the hypogastric route on the twelfth day. The bladder was sutured and a healing took place by first intention.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 18, 1909.

The Care of Club Foot in Infancy without Operation.—A. Ehrenfried's conclusions are as follows: (1). Practically all cases of congenital club foot are curable without operation if taken in hand before the child is six weeks old. (2). The younger the infant at the time of instituting treatment the better. (3). The results are better than if treatment is postponed until operation becomes necessary. (4). The routine treatment is manipulation followed by a plaster bandage every two weeks, progressively over-correcting the foot; as soon as the foot offers no resistance to over-correction and maintains the normal position naturally, continued manipulation, a tin splint to be worn at night, or a brace if the child is old enough to walk. (5). Relapses are bound to occur under any form of treatment if the after care is neglected; the patient should be kept under close observation for one year after apparent complete recovery.

A Review of Recent Experimental Work on Hemorrhagic Conditions.—This review is presented by W. P. Lucas, who says that some of the apparently unaccountable hemorrhages of childhood may be due to a chemical combination of the bile salts and the calcium salts, thus rendering the blood incapable of coagulating. In congenital or

hereditary cases the cause may be the absence of the tissue coagulins. Therapeutic measures viewed in the light of experimental evidence must supply the deficiency in each case or correct faulty performances of normal processes or act as stimulants for the production of such processes by the body cell. Calcium salts may be given by the mouth or subcutaneously, but experiments have shown that while the amount of ionizable calcium in the blood and this is the only form that counts, may be increased, this increase is so slight as to be unavailing. The use of gelatine is purely empirical. We have no evidence that it increases coagulability. Adrenalin as usually given is inert for it loses its power before it gets into the circulation. Subcutaneously there is no effect on the blood pressure, that is, no recognizable effect. Intravenously we get an increased pressure but this may increase the bleeding. Its action is entirely a mechanical one on the vessels, making osmosis more difficult by increasing the contractile tone of the vessels, especially the peripheral ones. In recent years the revival of blood transfusion promises more favorable results. These naturally follow more constantly in the hands of those surgeons who are operating all the time and who have acquired the necessary technical skill. The danger of this procedure is lessened if the blood is taken from a member of the patient's family. Horse serum is little powerful, rabbit's serum is more so, and human serum heads the list in potency.

New York Medical Journal, November 20, 1909.

Tonsil Removal.—E. V. Hubbard comments on the various views as to the tonsillar function and comments on the removal of the submerged variety. Obviously this should be as thorough as possible. He is not an advocate of some of the recent methods of deep dissection. He prefers the use of the cold wire snare and has devised a tonsil harpoon and a tenaculum to aid in thorough removal of the offending tissue; also a modified Mosely's snare and a special scissors to be used for blunt dissection. The use of the harpoon which has movable points is to raise the tonsil from its bed.

A Case of Uremic Amaurosis Following Scarlet Fever.—A case is reported of a boy of 13 years by A. C. Sautier, who says that this form of amaurosis is perhaps most often found as a complication of a post-scarlatinal nephritis. Almost invariably the eye lesion has occurred during the period of desquamation, being preceded and often accompanied by uremic manifestations, convulsions, vomiting, headache, etc. As a rule blindness sets in suddenly, involving both eyes, and is absolute. In most cases vision returns to normal with from one to three days. In most instances also the iris responds to the light stimulus even during the blind period. All of the reported cases who survived the constitutional affection recovered full vision. The case reported here was doing well in this respect when last seen. Vision may return and still the patient succumb to uremia. There has been considerable discussion as to whether the transient blindness of uremia is of cortical origin or due to a peripheral lesion involving the optic nerve or ganglion cells of the retina. Graefe laid particular stress on the retention of the light reaction and placed the lesion accordingly beyond the corpora quadrigemina, but cases since reported, in which there was no reaction to light, and a few cases in which the condition was complicated with visible peripheral lesions occurring synchronously with the amaurosis, suggest that under certain circumstances there may follow involvement of the peripheral ocular structures, optic nerve, or ganglion cells of the retina. The lesions have been variously ascribed to the effects of a transitory edema, to vasomotor disturbances, and to the direct action of the uremic poison upon either retina, optic nerve, or cortical cells. The latter hypothesis (the theory of uremic intoxication) is perhaps the most plausible one. While the results of post-mortem examinations have so far not led to any conclusive facts as to the nature or localization of the lesion, clinical evidence is in favor of attributing the condition in general to a cortical affection, including uremic blindness among the other cortical symptoms of the uremic state, hemiplegia, epileptiform convulsions, deafness, etc. Another factor in favor of such a hypothesis is the occasional occurrence of a typhoid homonymous hemianopsia.

Certain Contagious Diseases of the Skin.—F. C. Curtis refers specially to scabies, ringworm, tinea, and impetigo. He says that this class of diseases is spreading through the country, having gotten beyond the crowded centers of population. They are often unrecognized because they are new to a given locality and have changed their form under new conditions. In scabies the lesion is a multiform one for the reason that most of it is a secondary dermatitis. The areas involved are the interdigital skin, wrists, forearm, axillary folds, waist line, mammæ, genitals, and toes. The disease is found among those who are perfectly clean in their habits. Pullman car blankets frequently convey it. Ringworm is more common than formerly. It produces clinical effects according to the site of its growth; simple, on non-hairy-skin bald spots on the scalp, excessive folliculitis on the bearded face, and the extremely itchy eczema marginatum of the crural region. The last two have been the more common. The special region involved is along the line of the jaw and down over the bearded area of the front of the neck where the skin has a loose structure. All parasitic skin lesions should exclude school attendance. A week at home is long enough under proper care to destroy the infectiousness of a child. Ringworm is not so readily cured, but single cases yield. For scabies, the author recommends an ointment of one part styrax to two of lard. It should be preceded by a vigorous bath. For ringworm he advises mercurial ointment and iodine, the latter a one in ten solution in goose oil. Bichloride packs are not effective and moist applications in general are not desirable. For impetigo cases he advises frequent washings with soap and borax and a mild ointment of boric acid and ammoniated mercury. This disease is spread by barber shops and is seen more frequently than formerly.

Journal of the American Medical Association, November 20, 1909.

Pituitary Tumors.—A. B. Kanavel points out the difficulties of operating for tumors of the pituitary body according to the usual methods and proposes an operation which he thinks, after extensive study of the anatomy and repeated operations on the cadaver, offers an improvement on existing methods. It is an infranasal operation and the essential steps of it are practically as follows: "The nose is turned up and entrance made into the inferior part of the nasal cavity; the septum is cut along its inferior part and its attachments to the perpendicular plate of the ethmoid. The middle turbinates are removed and the septum deflected to one side. We thus have a perfect view of the field of operation on the sphenoid. The sphenoidal foramina are located, and the interfering attachment of the perpendicular plate of the ethmoid and the vomer are cut away. The anterior wall of the sphenoid cells is broken in, and by the aid of Hajek-Schmithuisen punch forceps the sphenoid cells are opened up and the tumor removed as in any other procedure." This method appeals to him for its simplicity, the minimum of time it takes, the control of hemorrhage, and the lessened chances of infection. The only real difficulty encountered was the variation in the sphenoidal sinuses and this of course is encountered in any transsphenoidal operation.

Cystocele.—G. R. White says that the reasons for failure of operations for the permanent cure of cystocele seems to be that the normal support of the bladder has not been sought for and restored, but that instead, an irrational removal of part of the anterior vaginal wall has been depended on for this purpose. The bladder rests on the anterior vaginal wall to which it is slightly adherent. The support of this wall is due to its attachment to the symphysis pubis and pubic bones in front, laterally to the white line of the pelvic fascia and ischiatic spine, and above and behind to the uterus. The uterus itself, being freely movable, is of little importance as a support and the real support of the vagina comes from its attachment to the white line of the pelvic fascia and especially a thick bundle of fibers attached to the spine of the ischium and radiating out on the anterior and posterior surfaces of the vaginal tube. If the fibers along the white line, and especially those from the spine, are divided, the vagina falls down and a cystocele results. It is easy to see how this can happen in difficult deliveries and he has had it occur under his eyes in a case of instrumental delivery. In the operation he describes: "The vagina is held open by two retractors, the ischiatic spine is located by palpation, and an incision from one to two inches long is made through the mucous membrane, parallel to the white line, and extending well up the vagina. The bladder is separated from the vagina by blunt dissection until the spine of the ischium and white line are reached and can be felt uncovered beneath the finger. Hemorrhage is seldom troublesome and can be controlled by a few minutes' pressure. The sutures, which are of chromicized catgut, are passed under guidance of the finger by a Deschamps handle-needle. The first suture goes back of the white line just as it joins the spine of the ischium. The handle-needle is taken off, and each end of the suture threaded on a separate needle; one needle is passed from within out through the median edge of the incision, taking a firm hold on the vagina; the other needle is passed in a similar manner

through the lateral edge of the incision. The two ends are then clamped and are ready to be tied. A similar suture is placed half an inch lower down on the white line, and when this is in place both sutures are tied, bringing the lateral sulcus of the vagina in contract with the white line of the pelvic fascia. Should there be any prolapse at the outlet of the vagina, the incision may be extended down alongside of the urethra and the vagina sutured to the dense fascia covering the pelvic bone. The opposite side is treated in a similar manner and when both sides are tied the anterior vaginal wall is drawn up in a normal position, and has no tendency to sag, even when the patient coughs or strains. The vagina reaches across from one ischiatic spine to the other, without any tension; it collapses when the retractors are removed and normal relations of the parts are restored." The advantages claimed for this operation are the restoration of the normal supports, no sacrifice of tissue, rarity of recurrences, and the fact that it can be done without interfering with any other plastic work about the vagina. In fact such work has been performed in connection with the operation in all the nineteen patients so far operated on. The article is illustrated.

The Stem Pessary.—J. H. Carstens advocates the use of the stem pessary in properly selected cases of amenorrhea, premature atrophy of the uterus, dysmenorrhea, and displacements. If amenorrhea is due to imperfect development, whether caused by poor hygienic living or otherwise, he has found so much benefit from the pessary that he has increased in the indications for its use ever since. When the morbid condition is due to premature atrophy from nonuse he has obtained great improvement by the insertion of a stem pessary, allowing it to remain for a year or more. To these cases may be added cases of superinvolution of the uterus following confinement or miscarriage which present about the same symptoms as the amenorrhea of puberty. There is still a third class of fleshy sterile women with nervous symptoms in which he has never seen any medicine do good but great benefit from the insertion of a stem pessary and proper hygienic measures. In the very difficult condition of dysmenorrhea we must see, first of all, that the pelvic organs are in normal condition, and if there is partial atresia only temporarily relieved by dilitation he always inserts the stem pessary to prevent recontraction. In membranous dysmenorrhea he thoroughly curettes the uterus and swabs it out with pure phenol and then inserts the stem and cures the patient. The so-called congestion and inflammatory condition usually means disease of the tubes or peritonitis, etc., and these require special surgical treatment. They do not need the stem pessary, which will be likely to do harm. It is indicated in those obscure cases in which we can not lay our fingers on any particular abnormal condition, the kind that used to be called neuralgic. In the other peculiar pain occurring just between the menstrual periods, which the Germans call *Mittelschmerz*, the pathology of which we do not understand, beneficial results are obtained by the use of the stem pessary. In his experience he has found that some cases of displacement in which there is a reflection or version, besides the other conditions requiring the use of the stem pessary, the latter has often helped the diplacement if worn long enough to enable the ligaments to regain their original tone. Sterility has also been relieved in some of his patients. Besides the contraindication already mentioned of congestion and inflammatory conditions, versions and flexions with adhesions and movable displacements also contraindicate it. All septic and inflammatory conditions would rightly exclude its use. Judiciously used it is a valuable aid, but injudicious use will bring it into disrepute. He gives his technic. Anesthesia is required and absolute cleansing of the vagina together with complete asepsis. The button at the end must be on the cervix. He uses the Chamber's hard rubber stem, though others may be as good, and keeps his patients in bed as a rule for forty-eight hours after insertion. Then they can get up and go about their usual vocations and never feel conscious of the presence of the instrument.

Opacities of the Cornea.—C. W. Cutler insists on the importance of examining for small lesions of the cornea in children by the general practitioner. In dealing with the eyes of children he says that it is important to remember that while epithelial damage is not vital, any infection or injury passing Bowman's membrane will leave an indelible trace, menacing vision if it lies within the area of the pupil. He describes the method of examination which may be difficult with a resisting child. But if there is a history of eye trouble and secretion on the lids or the child shuns the light or resists opening the lids, the cornea must be thoroughly inspected. This requires a good light and a lens, not for magnifying but to focus the light on the cornea. A little practice will suggest modes of procedure, varying with the case. There are three points to be considered in examining the cornea: the corneal reflex, the smooth surface, and the transparency. Any clouding of the normal glistening reflex indicates an active process, edema or infiltration, and any depression or defect of the surface indicates an ulcer. All infants with purulent discharge should be treated as though they had gonorrhea and special care should be taken in cleaning out the secretion not to spread the infection. The nutrition must be looked after and Cutler advises continuance of nursing if the mother is intelligent and can protect herself. Phlyctenular conjunctivitis is mentioned as an important matter as it appears insidiously and often is not detected until serious damage is done. Its tubrculous nature in the large majority of cases and its tendency to recurrence in conditions of lowered vitality are noted. Syphilis is also a potent cause of corneal opacities and the traces it leaves are as characteristic as Hutchinson's teeth. Special precautions in the management of the lids are emphasized as well as the examination with a lens by oblique illumination, which is easily acquired and should be practised in all cases in which the eyes show signs of irritation and as a means of diagnosis in obscure cases in which tuberculosis or syphilis is suspected.

Eye Symptoms in Pellagra.—From an examination of the eyes of fifty-five patients suffering with pellagra in the Peoria (Ill.) Hospital of the Insane, C. B. Welton finds that paralysis of the eye muscles occurs in the later stages in a small percentage and that conjunctivitis is not uncommon. Early forming cataracts are frequent. Inflammation of the optic nerve and retina is observed in a relatively large percentage of patients. Involvement of the choroid is common and is the most marked of all the eye changes. In none of the patients with eye symptoms could these be considered as pathognomonic of pellagra. The severity of the eye symptoms runs parallel with the general manifestations of the disease and renders the prognosis more serious, indicating in a large percentage of cases an early fatal termination.

The Lancet, November 13, 1909.

Removal of Foreign Bodies from the Stomach.—B. Pollard gives the following experience in removing foreign bodies from the stomach: The operator opened the abdomen by a longitudinal incision through the upper part of the left rectus muscle and seized the body (coin) through the wall of the stomach with his finger and thumb; an assistant passed a flexible forceps by the mouth into the stomach. The coin was adjusted in the grip of the forceps and care was taken to avoid the inclusion of the mucosa. Forceps and coin were then withdrawn together. The instrument used is on the type of Toynbee's ear forceps. The blades when uncontrolled spring apart, one fixed to a piece of copper wire around which a tube of spirally coiled wire is placed. The instrument is operated by the handles in such a way that the wire tube slips over the blades of the forceps and brings them firmly together. This method has the great advantage that it does not require opening the stomach.

The Enumeration of Blood Corpuscles by Simplified Methods.—R. Samut speaks of the tediousness of counting the cells in the squares of the Thoma-Zeiss instrument and commends the use of the Blenden-Ocular "Ehrlich." An ordinary No. 2 ocular is provided with a screen which cuts out a little square from the field of vision of the ocular. By means of a little knob this square can be narrowed to and reduced to 0 and by means of notches which divide one side of the square into four parts the reduction may be effected in exact proportion. In using the device a drop of blood is put on the Thoma-Zeiss slide in the usual way and allowed to stand five minutes. A No. 9 Leitz objective is used, and the ocular, the slit being adjusted by means of the knob so that four squares of the central platform of the counting chamber just coincide with it. The number of cells is counted and the preparation may be adjusted as many times as desired, each count representing the number of cells in four squares since the slit exactly corresponds to four of the squares. The total number obtained after several such counts being divided by the number of counts gives the number of red cells per field of four squares; hence division by four gives the number per square. A method is also described for the estimation of the number of leucocytes.

Radium in the Treatment of Cancer and Associated Conditions.—H. T. Butlin gives an account of his results in four cases of epithelioma, one case of a doubtful nature and three of leucoplakia. Of the epitheliomata none were permanently benefited except one which was of a very small size. The benefit to the patient was, however, very great. Two patients whose cases were deemed

suitable for radium treatment by the dermatologist in whose hands they were, did not benefit. As far as the author knows, the case first mentioned is the only authentic case in all England of a true epithelioma cured by radium. The doubtful case, one of suspected epithelioma of the penis, was apparently cured. Of the three leucoplakia cases two were cured and one benefited. Yet the author prefers to say that he does not yet know whether to advise patients suffering from leucoplakia to submit to radium treatment or not. He says that radium cures these lesions only by substituting thin scar tissue for them, but it does not restore the mucous membrane to the condition it was in before the development of the lesion. Radium has the great advantage over surgery, however, in that it is almost painless and that no inflammation or open sores are produced when the applications are made by experienced operators. Radium is admirably adapted for rodent ulcers of small or moderate extent. The application is practically without pain and there is very little danger to life or health. It is also possible to procure the healing of epitheliomatous ulcers of very small extent and to remove the induration around the ulcers. It is doubtful whether radium will affect lymphatic glands or not even if it heals up the primary lesion. Whether the application of radium over the glandular area before it is obviously affected will be found to exercise a protective effect or not, the author does not know. At present the glands must be treated as heretofore, by excision.

Typical and Fractional Pneumonia.—Clifford Allbutt says that as there are no two individuals exactly alike so there are no two cases of the same disease exactly alike. So, too, diseases do not confine their lesions to the exact anatomical bounds marked out for them in medical treatises. Our diagnosis must be made by a comparison of the grouping of the various symptoms. The "type" case is the one which we never actually see either in bed or in book. Many groups of symptoms drop out of the reckoning in a given case. For instance cough and expectoration may be wanting in a given case as in old persons or in the insane, and with the evasion the febrile group may also be absent. We may perceive that in one case cardioarterial, vasomotor, and gastric symptoms are due in great measure to irritative processes in the bulb while in another they are due severally to direct impairment in heart, lung, or stomach itself. Organisms may often go long astray from their usual habitat, as the *B. coli* for instance, and sometimes the pneumococcus is found in the knee joint. Two illustrative cases are given. Case 1 was that of a young woman who was taken with obstinate vomiting, rapid pulse and respiration, and occasional sputum. She defervesced on the sixth day. Not until the fourth day was it possible to detect a small patch of pneumonia in the axilla. She had scarcely any fever and her symptoms appeared due to a medullary disturbance. There was no delirium whatever. Case 2 was that of a young woman in whom the toxins seemed to spend themselves particularly on the cerebral centers as she was semi-comatose, had violent delirium with contracted pupils, and occasional twitchings. It was not possible to make out signs of pneumonia till the third or fourth day and then only over a small and indefinite area at the back of one lung. She also recovered, the crisis coming about the sixth day. A recurrence of the hepatization was followed by a return of the cerebral symptoms, but eventual recovery ensued. Persistence and severity of the chest pain are in the author's experience bad omens. In fact he regards it of almost fatal significance. He is disposed to think that in these cases there is a mixed infection, perhaps streptococcic.

The Treatment of Chronic Ulcer of the Leg.—W. Evans thinks that when a traumatic ulcer will not heal there is some such factor as sepsis behind it or perhaps the unfavorable influence of varicose veins. He also believes that 90 per cent. of these sluggish ulcers are due to syphilis. The cremation of the margin is another feature of these specific sores. In such cases the amount of alcohol consumed should be reduced to the lowest possible limit. Mercury and the iodides should not be given internally together. Organic iodides should be preferred to the metallic. They should be well diluted and may be alternated with courses of strychnine particularly when, after a period of improvement, the ulcer becomes sluggish. If the two remedies, mercury and the iodides, be given together, the red iodine may occur in the system and much pain will be felt in the ulcer. For a general antiseptic application the author advises a dram of boroglyceride in half a pint of hot water. Locally, mercurials may be used in the form of the black or yellow wash, or we may use solutions of carbolic, 1 to 100, or even iodine tincture, diluted one to 4 or 5 of hot water. For ointments the ammoniated mercury or the yellow oxide are preferable. If the dry treatment be preferred three drams of zinc oxide and half a dram of calomel may be mixed with enough "*kieselguhr*" to make an ounce. *X*-rays have benefited some cases. There are some ulcers which resist cure even when given a long rest. This is probably due to the tethering of the ulcer edge to the underlying bone. To free these edges fomentations should first be used to reduce the septic complications of the ulcer; then the whole of the ulcerated surface should be scraped with a Volkmann's sharp spoon and the whole of the edge undercut with a scalpel. The edges may then be drawn together and if at the same time the margin of the skin is freshened, a very thin border being cut off, the healing process will probably start afresh and the granulation will be rapid and sure.

British Medical Journal, November 13, 1909.

Spontaneous Post-Mortem Delivery.—J. B. Wilkinson reports the case of a young robust unmarried woman who committed suicide on account of pregnancy. Her body was discovered floating on a warm water reservoir near a large mill. It was removed and laid out for burial on a Saturday. Decomposition had already set in, parts of the body being quite discolored. The mortuary was then closed till Monday, when it was discovered that the woman had given birth to a seven-months child still attached by the cord to the body. The body of the child was but partly discolored, while that of the mother was quite black, and the abdomen was much distended with gas.

The Etiology of Epilepsy.—A. King says that all epilepsy is not due to one cause but believes that it is due to a complex of interacting causes, and probably the factors are not in relative proportion in all cases, that is, a person with nervous instability would require a smaller dose of toxin to cause an explosion than another with a firmer and more poison-proof nervous structure, while impaired intestinal function would further pathogenic growth, etc. Furthermore, the alimentary channel may not in all cases be guilty as a contributory party. But the author holds that at times there is circumstantial evidence of it, and in these cases it is not unreasonable to infer the existence of something entogenous (at least not immediately introduced) and that something to be a low order of vegetable life. Treatment based on this theory has, in the author's experience, been attended with good results. Among the various remedies which at different times have been proposed are the zinc salts, salicylates, creosote, borax, tar (a lay remedy) and the sulphocarbolates.

Present Position of the Neuron Theory Doctrine in Relation to Neuropathology.—This subject is discussed in an elaborately illustrated paper by F. W. Mott. A neuron is a nerve cell, and all its processes, including protoplasmic processes or dendrons and the axis cylinder process with its cone of origin, its collaterals or side-branches, and its terminal arborization. The neuron theory is that the nervous system consists of innumerable such anatomically independent nervous units in contiguity but not continuity. The author believes that the trophic and genetic independence of the neurons has been established. The question arises how are they connected with one another? The method of Golgi appeared to show that the neurons are arranged in systems, and numerous experiments were made to show that the dendrites exercised ameboid functions and little buds or gemmules on the processes of these cells were supposed to appear and disappear owing to the contractility of the protoplasm, thus leading to varying degrees of contact influence of one neuron upon another. In the lower orders of life there is a fibrillary continuity through several ganglion cells. As we rise in the scale of life it becomes increasingly difficult to demonstrate such a continuity though it would have certain functional advantages, did it exist. Are the number of fibers in the pyramids of the medulla equal to the sum of all the fibers in the anterior roots? Clearly the fibrils of the Betz psychomotor cells must be connected with a number of spinal motor neurons forming the common final patch for a multitude of different voluntary muscular activities. Moreover we know that there is not a direct connection between the upper cerebral neurons and the lower spinal motor neurons for intercalary neurons with axons which do not leave the gray matter intervene and the terminal arborization of sensory afferent neurons, cerebral, mesencephalic, and bulbar efferent neurons combine with spinal association neurons, through the intercalary neurons, in augmenting and inhibiting the outflow of energy of the spinal motor neurons whereby the most varied, refined, and complex muscular reactions in adaptation to environment are effected. The nervous energy is expended in the gray matter of the brain and spinal cord. Other points re-

ferred to by the author are the significance of the nodes of Ranvier, theories in reference to the functions of the interfibrillary chromophilous substance of the ganglion cell and the dendrons. Is this chromophilous substance the source of the energy, and if so, is it used at the site of its formation or is this substance, which in the dead cell corresponds to the Nissl granules, a store of energy-producing substance in the latent state analagous to the preferment of the sweat glands, a substance which is transformed into the active energy-producing substance at the terminal arborization of the neurons? In general the author regards the neuron theory as resting on a surer basis than ever before.

Berliner klinische Wochenschrift, November 1, 1909.

A Case of Sporotrichosis of the Skin.—Arndt reports a case of sporotrichosis of the right forearm. The differential diagnosis is discussed, which was finally determined by smears and cultures in which the characteristic threads and ovoid spores were found. Sporotrichosis may occur in solitary local lesions or as a disseminated disease. The disseminated disease is more common. It occurs without general symptoms or especial subjective discomfort as very numerous (50-80) round, hard, painless nodules, freely movable in the subcutaneous tissue, over which the skin is normal. As these grow they involve the skin, which is at first pale red, then deep red, even blue red; the center is elastic and later fluctuates. The nodules may remain as such for a long time, finally, however, they perforate and form ulcers, which may be either clean-cut, with infiltrated edges, or, more commonly, with irregular jagged border, not infiltrated, bluish, and undermined. These may remain if untreated for a long period. They heal with a smooth scar of bluish color and pigmented at their edges. The prognosis under treatment is good. The therapy consist of potassium iodide 30 to 60 grains a day, which causes recovery with remarkable rapidity. Whereas the skin and subcutaneous tissue is the most frequent site of the disease, it may occur also in muscles, bones, or joints; in the epididymus, larynx, or eyes. It is probable that sporotrichosis of the lung may occur. In these organs the clinical diagnosis is especially difficult.

Laboratory Infection with Cholera Vibrio Obtained from Water.—Zlalogoroff reports the case of a woman of 27 who as a student in St. Petersburg was working in the laboratory with water from the Neva. To do agglutination experiments, she made an emulsion of a vibrio grown from this water, and in her experiment sucked into her mouth from her pipette about 0.1 c.c. of it. At the end of fifty-eight hours she developed a diarrhea which increased, and was associated with heart weakness, cold, and cyanotic extremities, but no abdominal pain. The stools showed vibrios which were obtained in pure culture and agglutinated at 1:5000. After two days the diarrhea stopped and in ten days the patient was discharged. Numerous previous cases of laboratory cholera are cited, all of which occurred from vibrios obtained from man. This is the first case of a water-borne vibrio producing the disease in the laboratory.

Deutsche medizinische Wochenschrift, October 28 *and November* 4, 1909.

Serological Studies of Infant Feeding.—Noeggerath has studied the colostrum and milk from thirty women in respect to the complement content described by Pfaudler. As a result of his investigations he states that woman's milk may, without doubt, contain complement, but that this occurs only in traces and irregularly. In the milk of many women there was never any complement demonstrable during the entire period of lactation, without this absence in any way interfering with the curative or nutritive value of the milk as compared to other women. In colostrum from his investigation he was never able to find complement. Investigations of a large series of infants' blood sera showed similar results, that a complement might be found, but this was not the rule, and was not especially common, on the contrary, not uncommonly he found quite negative results. Finally he found that the presence of complement in the sera of the infant bore no relation to its constitution or to the form of its nourishment. These results disagree with the earlier findings of Pfanndler.

Comparative Measurements of Blood Pressure by the Palpatory and Auscultatory Methods.—Sterzing compares the common method of sphygmometry with the modification in which instead of feeling the pulse the pulse tone is heard by means of a phonendoscope. By listening below the constricting cuff of the manometer on the reduction of the pressure, a pulse tone is heard when the circulation commences. This represents the point of maximal pressure. The disappearance of the tone again represents the diastolic pressure. The method is much better than the palpatory in cases in which the pulse is small and hard to feel, especially in fat persons, children, and with a weak heart. The systolic pressure registers several m.m. higher than by palpation and the diastolic considerably lower. One hundred cases were investigated. The author concludes by stating that the method does not give absolute blood pressure, but does designate accurately any rise or fall therein. The auscultatory method requires no extra apparatus, and is easy to learn. It is recommended for clinical work, especially when the diastolic pressure is desired.

Tearing of the Rectum in Fracture of the Pelvis.—Harras reports two cases in which in a fracture of the pelvis the rectum was torn away from the anus. From experiments on the cadaver he finds that tremendous force is required to separate the anus and rectum, if the power is applied to the former, and he therefore offers the theory that this accident is probably the result of a direct pinching of the lower rectum between the two halves of the pelvis at the time of the accident. The organ is seized by the traumatic approximation of the two tuber ischii, and is thus torn away from the anus.

Prognostic Significance of Blood Pressure in Diphtheria.—Brückner has studied the blood pressure in two hundred cases of diphtheria, taking daily records with Gartner's tonometer. He found a regular course of the blood pressure, without daily variations, to occur in both the uncomplicated cases and in certain of those with mild cardiac involvement. Cases with irregular blood pressure curves showed various clinical pictures. They occurred in uncomplicated cases when the variations were not over 15 mm. and in the milder myocarditis cases. In every case marked falls of pressure were associated with definite signs of myocarditis. Falls of as much as 50 mm. appeared only with severe myocarditis. This was the greatest drop observed in which recovery occurred. The steady, progressive fall of pressure was present in the fatal cases. In every case, with one exception, the marked falls in pressure were accompanied simultaneously by signs of cardiac involvement; in one case only did the fall precede the clinical signs.

Tuberculosis in Infants.—Mallinckrodt on the basis of recent literature and his own observations states that tuberculosis in infants localizes itself first in the lungs, whereas the digestive tract is usually a secondary infection. The source of infection is the tuberculous surroundings; not the food. Most important is the significance of von Pirquet's reaction for the recognition of tuberculosis in the infant, in spite of Schlossmann's statement that this was merely a simplification, not an improvement, of the subcutaneous method. For the practitioner and the clinic, every simplification is an improvement, and without the cutaneous reaction the early diagnosis of tuberculosis in the well nourished nursling is not possible.

Preventive Vaccination in Bacillary Dysentery.—Ch. Dopter says that epidemics of bacillary dysentery in localities where the people are ignorant and have no knowledge of hygiene spread very rapidly. Isolation is impossible, and disinfection of the discharges cannot be efficiently carried out. Attempts have been made recently to prevent its spread by obtaining immunity by preventive vaccinations. In a family in which the disease has shown itself we may prevent its spread by injecting under the skin of each person ten cubic centimeters of anti-dysenteric serum. A single injection is not sufficient and should be repeated in eight or nine days. Vaccination may be done with serum or with serum-virus. Both are efficacious, but the use of serum is attended by no local or general reaction due to the bacilli of dysentery.—*Le Progrès Médical.*

Oxygen in Serious Cases of Whooping-Cough.—E. Weill and G. Mouriquand describe their experience with the use of oxygen by inhalation in serious cases of whooping cough and in pneumonia following this disease. It will serve to prevent the occurrence of pneumonia in many cases that are threatened with lung involvement. It also diminishes the severity of the paroxysms of cough, although it does not seem to lessen their number. Their cases amount to thirty and in all of them oxygen seemed to act as a sedative of the first order. It acts not as a depressant of the system, but enables it to struggle against the disease. Cyanosis is lessened, appetite is better, and somnolence diminished between the attacks. It acts as an antiseptic in the lungs, and prevents the extension of pneumonia to new localizations.—*Lyon Médical.*

Book Reviews.

Minor and Operative Surgery, Including Bandaging. By Henry R. Wharton, M.D., Surgeon to the Presbyterian Hospital, and the Children's Hospital; Consulting Surgeon to St. Christopher's Hospital, the Bryn Mawr Hospital, and Girard College; Fellow of the American Surgical Association. Seventh edition, enlarged and thoroughly revised, with 555 illustrations. Philadelphia and New York: Lea & Febiger, 1909

The general plan and arrangement of this edition are the same as in its predecessors; but the book has undergone some necessary revision. Matter now obsolete has been omitted, and new material and new illustrations have been inserted. Some new surgical procedures are incorporated, among them are two, the omission of which we noted in our review of the last edition; viz., the treatment of ingrowing toenail, and the removal of foreign bodies from the nose, ear, etc. This small volume is a standard work and, in spite of its title, it contains practically all the surgery that the general practitioner requires.

A Text-Book of Materia Medica, Pharmacology, and Therapeutics. By George F. Butler, M.D. Professor and Head of the Department of Therapeutics and Professor of Preventive and Clinical Medicine, Chicago College of Medicine and Surgery, Medical Department Valparaiso University. Sixth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1908.

As this book is now in its sixth edition it has apparently met the requirements of the physician and medical student of this country, possibly due to the fact that such a large amount of information is contained in such a relatively small space. The book is arranged for a reference book, not for a book to be read. The study of materia medica in its classical form vies with anatomy in being the most dry, uninteresting, and difficult to learn of all the branches of medicine, and this, too, when the science of the action of drugs upon the animal body can be made one really of fascinating interest if properly taught. In the first part of the book appear the pharmaceutical preparations, six pages of syrups and five more of elixirs, with long lists of tinctures, fluid extracts, pills, *et cetera*. The drugs themselves are classified according to their physiological action, a method very desirable in a book which is to be read consecutively, but in a reference book making an index quite indispensable. The book gives one the impression of being a reduction of the pharmacopœia with very little new which has appeared since the former edition of that most useful book. For example under bismuth we find no mention of that drug's important use in *x*-ray examinations, or of the cases of poisoning which have followed that use. Calcium chloride and lactate, two widely used drugs, are not mentioned. An effort is made to give the pronunciations of the names of the drugs, but unfortunately there are so many errors in the indications of the Latin quantities that it would have been better had this feature been omitted entirely.

Medical Gynecology. By Samuel Willis Bandler, M.D. Fellow of the American Association of Obstetricians and Gynecologists; Adjunct Professor of Diseases of Women, New York Post-Graduate Medical School and Hospital; Associate Attending Gynecologist to the Beth Israel Hospital, New York City. Second Revised Edition. With Original Illustrations. Philadelphia and London: W. B. Saunders Company, 1909.

Operative gynecology is a special field of practice and is well represented by special treatises in the literature of medicine. On the other hand, every general practitioner is called upon to do a great deal of nonoperative work in gynecology and it is his side of the matter that forms the subject of Dr. Bandler's book. The author has not merely given the usual facts in the symptomatology, diagnosis, and treatment of gynecological affections but has paid very earnest attention to the anatomical and physiological peculiarities of women that form the substratum of these affections. His work is, therefore, more than a text-book; it is a logical presentation of the relation between causes and effects in the deviations from the normal conditions in the sexual organs and functions of women.

The first portion of the book is taken up with the consideration of the principles of gynecological examination and the methods of medical treatment. The latter subject contains not merely the more usual therapeutic procedures, but a careful presentation of hydrotherapeutic measures, massage, mechanical treatment, such as supporting bands, corsets, etc., hyperemia, and mineral waters. Then the following special conditions are studied *in extenso:* Disorders of menstruation, uterine bleedings, pelvic pain, sterility, disorders of urinary functions, associated nervous disturbances, constipation, gonorrhea, syphilis, and finally affections of the special structures belonging to the urogenital system of the female. Presentation of the symptoms of each affection is followed by a careful analysis of their causation and only then the treatment directed to the removal of the causes is described. Symptomatic treatment is, of course, not neglected, and the practical value of the book for the student or the busy practitioner is enhanced by the recital of specific measures and actual prescriptions used in the practice of the author.

Practical Dietetics. With Special Reference to Diet in Disease. By W. Gilman Thompson, M.D. Professor of Medicine in the Cornell University Medical College in New York City, Visiting Physician to the Presbyterian and Bellevue Hospitals. Fourth Edition, Illustrated, Enlarged and Completely Rewritten. New York and London: D. Appleton & Co., 1909.

In the fourth edition of this work we find over one hundred pages added to the first edition of 1896. All of the text has been rewritten and revised and much work has been necessary to bring the subject matter thoroughly up to date. The arrangement, however, is essentially the same, the first part dealing with food and food preparations and giving complete information such as clinicians desire to know; Part II takes up stimulants, beverages and condiments. The author here takes up the middle ground position with reference to the value of alcohol. Part III deals with cooking, the preservation and preparation of different foods, and the quantity necessary under different conditions. In the fourth division he considers special states, such as childhood and age, race and heredity, and their relationship to food. The next chapter takes up food digestion and the various influences which affect it, pointing out the influences of emotion, excessive mastication, and the general physiology of the digestive processes. Part VI deals with insufficient feeding, overindulgence, poisoned foods, idiosyncrasies toward various articles of diet, etc. The next parts, the most interesting, and the parts where the author is at his best, take up the questions of diet for the sick, what foods and methods of feeding are best fitted for certain diseases, dealing with these affections separately and practically. The advice is sound, not too fixed or rigid, and the author shows his bedside experience and ability to recognize that the sick patient may have preferences that are sometimes wisely consulted. An appendix and index complete this work of over nine hundred pages.

The book may be recommended as safe and sane, thoroughly up to the times, practical, and interesting. It is equally well adapted to students, general practitioners, and specialists. To the student much new knowledge is offered, to the practitioner plenty of detail which he can use and which he should know; to the specialist it gives a breadth of view and points out the limitations of unperfected science.

Diseases of the Personality. By Prof. Th. Ribot, Paris. Translated (with Homeotherapeutic Annotations) by P. W. Shedd, M.D. New York and Philadelphia: Boericke & Tafel, 1909.

Prof. Ribot is not a physician, but a pure psychologist. His work on "Diseases of Personality" has reached its fourth edition, and continues of interest as psychology. The young homeopathic translator, however, in his enthusiasm states in the preface that while Prof. Ribot himself "is quite unacquainted with homeotherapeusis," his work is most illuminative of it. It may, therefore, be of peculiar value to the homeopathic practitioner.

The Proteins. By T. Brailsford Robertson. University of California Publications in Physiology, Vol. 3, No. 16. Berkeley: The University Press, 1909.

This monograph contains the Herzstein Lectures of the University of California for 1908-1909. The first lecture is devoted to the chemical structure of the proteins as based upon the work of Fischer and his pupils and the synthetic formation of the polypeptids. The second and fourth lectures are devoted to a consideration of the physical chemistry of the proteins in its relation to the viscosity of their solutions, and the action of heat and other agents in coagulating them; their osmotic pressure and dissociation constants. The third lecture is devoted to the compounds of the proteins with alkalies, acids, and dyes. The fifth lecture reviews the main facts about hydrolysis by acids, alkalies, and ferments, and also the reversal of this process; that is, the synthesis of proteins by the ferments. The pamphlet, therefore, offers a convenient review of the subjects mentioned for those interested in the recent chemistry of the proteins.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 25, 1909.

DR. H. SEYMOUR HOUGHTON IN THE CHAIR.

THE evening was devoted to a symposium on infant feeding.

Biology as the Basis of Infant Feeding.—Dr. HENRY DWIGHT CHAPIN considered it unfortunate that there was not a common standard of infant feeding. In one locality the calorimetric basis was advocated, thus making the problem of infant feeding one of physics; in another locality the percentage method was in vogue which made the problem largely one of mathematics, and in still another place the efforts at the solution of this problem took the form of chemical manipulation, such as the addition of citrate of soda, etc. While it was true that physics, chemistry, and mathematics might play a part in the problem of infant feeding no one could successfully feed infants by confining his efforts to any one of them. Infants had been fed successfully by all of the methods that had been proposed, but analysis showed that other factors than those given prominence had been involved in such success. The problem of infant feeding belonged to biology, the science of living things, and not until infant feeding was treated from this point could there be a common ground for teaching and discussion. In studying the life history of all forms of animals it was observed that all commenced life in an exceedingly simple form and for a time their development proceeded along lines so nearly parallel that it was impossible to determine to what species the embryos belonged. As development proceeded a divergence of form and structure was noticeable. This divergence was so great that at birth there was no difficulty in distinguishing species. The variation in the function of nutrition at this time was not so very great, especially in mammals. At birth the milks of different mammals could be made interchangeable for many individuals of the young of various species, but at the end of the suckling period no such interchange of food would be possible. To realize what a divergence in the digestive functions had taken place during the suckling period, imagine an infant, a calf, and a kitten all being fed successfully on cow's milk. It was evident that during this period the difference in their digestive powers was not very great, but in one short year the divergence had been so great that the natural food of the calf was then wholly unsuited to the infant or the kitten, yet the chemist found that the foods of all three at this time contained the same basic nutritive elements as at birth. An important matter which seemed to have been generally overlooked in infant feeding was that milk was a food for a digestive tract that was constantly changing its form and function, and that the differences in the digestive properties of the milks of various species were for specific purposes. The relation between the placenta and the infant was so evident that their perfect adaptation attracted no attention. Few seemed to realize that problems of infant feeding centered largely around the adaptation of the mammary secretions to the developing stomachs, and that the mothers' secretions adapted themselves to developing stomachs that were rapidly diverging in form and function. While the fats and carbohydrates in different milks in their composition and reaction to the digestive secretions were a good deal alike, the proteins were essentially different. The protein might coagulate in a solid, gelatinous, or flocculent matter. Biological science showed that while there was a certain amount of protein present in the milk of all animals which was necessary for tissue building and growth, this protein must not only be coagulable, but must curd in a certain specific way in each species of animal. The protein was thus the least readily interchangeable of the ingredients of milks of different species. The protein had a developmental, as well as a nutritive function, to perform. While immediate nutrition was of great importance to the growing infant one must not put all food in a form for quick absorption and neglect to give proper work for the secretions and musculature of the digestive tract. From the biological standpoint the main points to be considered in infant feeding were, a sufficient supply of proteins to permit the production of new tissues, enough energy food to supply the necessary amount of energy to carry on the vital processes, and the adaptation of the form of the food to suit the peculiarities of the individual infant. This adaptation must be brought about by some of the means already indicated, either chemical, mathematical, or physical, or a combination of these various methods. Infants did not perform work outside of the internal work of the body and hence did not need food primarily for its energy contents, nor for its heat producing effect. Biology taught that no two animals or plants were exactly alike; hence no fixed and absolute rules for the feeding of infants could be laid down. Different forms of food might be developed from time to time and different methods of feeding might be advocated, but their success would depend on conforming to a few simple laws that applied to all animals, and biology alone could furnish those laws. Before any of the details of infant feeding could be accepted as scientific and thus of permanent utility, it had to be decided in how far they were in accordance with biological laws. Biochemistry, physics, and quantitative manipulations all had a certain value, but one must be careful to put them in their right relation with each other and not over-emphasize any of them. Emphasis was always to be placed upon true tissue forming material in a body that was undergoing rapid growth. This was the defect of measuring food values on a calorimetric basis for the young when growth should form the principal factor for consideration.

Pasteurization of Milk.—Dr. ROWLAND G. FREEMAN said all were agreed that what was wanted was a safe raw milk, and hence the only question for discussion was whether we could obtain a safe raw milk for feeding infants, and, if not, whether milk was injured by heating, and to what extent, and by what temperature. It was possible to secure a much safer raw milk to-day than it was five or ten years ago in New York. Tuberculosis was one of the lesser dangers in milk under present dairy conditions. The diseases concerning which we had most tangible and incontrovertible proof were typhoid fever, diphtheria, scarlet fever and epidemic sore throat. Our sanitary dairies did almost all that was possible to protect from these diseases, but epidemics still occurred from the sale of certified milk. Dr. Freeman believed that at the present time there could be no absolute safety in raw milk. The opinion had become current that heated milk produced poorly nourished children, that it produced rickets and scurvy, that it killed the life of the milk and produced chemical changes in the milk which rendered it less nourishing. These opinions did not prevail abroad. European physicians had been using it for twenty years without having made a similar observation. Although scurvy had developed in children fed on heated milk, the milk was not at fault. Out of 356 cases of scurvy studied by the American Pediatric Society in 1897, 60 per cent. were fed on proprietary foods, 19 per cent. on sterilized cow's milk, 10 per cent. on condensed milk, 3 1/3 per cent. on breast milk, and only 4½ per cent. on pasteurized milk. These figures indicated very little responsibility on the part of sterilized milk for scurvy. Scurvy developed to a great extent when extreme dilutions were being fed. Comby of Paris, in a very large experience, had seen only five cases of scurvy and those babies were all fed on diluted milk. The assumed relationship between the heating of milk

and scurvy was unfounded. Rachitis had very little to do with feeding, but was due to lack of fresh air, for it was a disease only of cold climates and developed in the winter. It occurred with all sorts of foods. The ordinary commercial pasteurization of milk was to be condemned. The only safety for the consumer was to get his milk sweet and raw, and then to render it safe by the smallest amount of heat compatible with safety. A temperature of 140° F. continued for forty minutes would kill all bacteria that were known and feared in milk. This changed neither the taste nor, so far as was known, the chemical composition, nor the ferments of the milk. Such pasteurization should be still used by every physician who was conscientious in his endeavor to secure the safety of the infant he was feeding.

The Percentage Principle as Applied to Infant Feeding.—Dr. Henry Koplik reviewed the work of Biedert and Meiggs who were the first to attempt to apply percentage methods to infant feeding. The fact that the field of infant feeding to-day was still in many spots untilled soil showed that these methods, as others which had succeeded them, did not meet all cases, and their abandonment was the truest estimate of their ultimate value. However, the physician had learned to think in food elements and in percentages, and this was a step in advance. The intelligent use of the percentage method presupposed a knowledge, on the part of the physician, of the effect of the various percentages of fat and protein on the infant. An injudicious use of formulæ might upset an infant beyond all remedy. Though the percentage method was a great step in advance in the education of the physician as to the exact composition of the infant's food, it told him little beyond a few primary facts as to how he should feed an infant. The teaching of the percentage method was that the physician must begin with a low percentage of protein, fully one-half of 1 per cent., and, as the infant reached the end of the first month, the percentage was increased to 1 per cent. The newborn infant would digest 2 per cent. of fat, and a few weeks after birth 3 per cent. of fat. The sugars were given in 5 to 7 per cent. mixtures. Most infants would thrive on such a feeding. The exceptional infant, the one on whose account all the agitation and the investigation in the science of infant feeding had its origin, would not thrive if simple formulæ failed, on any variation of the percentage formulæ. The fault lay, not in the failure to strike the correct note in percentages, but in the infant's inability to digest cow's milk. If, in such instances, one persisted in changing one or the other percentage, the infant began to show more and more palpable signs of nutritional disturbance, in the form of flatulence, colic, sleeplessness, loss of weight, and deterioration of tissue. The insistence of the advocates of percentage feeding upon a low protein percentage for early infancy was met with equal positiveness by such as Czerny, Veriot, Budin, Keller, and Escherich who could not see that the old theory of the indigestibility of the curd of cow's milk had been proven. According to the authorities there was no one symptom, in all the gamut of symptoms of nonassimilation in artificially fed infants, that could be traced to the proteins. They pointed to the great tolerance of infants for high protein percentages as seen in buttermilk mixtures and malt soup mixtures. The percentage method had simply given the physician a means of obtaining a food accurately put together. It had shown him that he could give to young and old infants certain percentages of proteins and fats. If he exceeded certain limits certain disturbances would result. To feed an infant successfully the physician must be thoroughly at ease in regard to the tolerance of certain infants of the fats of cow's milk, and the disturbances which resulted from the ingestion of the fats of cow's milk, as compared with human milk. Nature, in the breast milk, presented a food average, but ever changing percentages of fats and proteins. A woman's milk not only varied from day to day, but from hour to hour, and still the infant throve. This should teach us that the kernel of infant feeding did not lie in the percentages, relative or otherwise, of the proteins and fats in the food, but in the nature of these proteins or fats. Success in infant feeding did not lay in any particular method of feeding; it was the individual infant that the physician was called upon to feed. Else how could one explain the fact that given two infants, fed on the same breast, one would thrive, and the other would not. The last word on the percentage method of feeding to-day was that it was a means to an end. This end must be attained through a thorough knowledge of physiological chemistry of infant feeding. It had the standing of a prescription which was dictated by an intimate knowledge of the capabilities and deficiencies of the assimilative powers of the infant to be fed.

The Feeding of Infants During Illness.—Dr. Linnæus E. La Fétra stated that no matter to what class of cases the patient belonged it was the individual that was to be fed, and that his peculiar reactions to foods, his susceptibilities, and, to a degree, his appetite was to be considered. In considering the physiological and pathological actions of foods, Dr. La Fétra said that in order to be assimilated food must be digested; to be digested it must be brought into solution or fine emulsion; it must therefore be either in minute subdivision or in liquid form. The sight, odor, and taste of food stimulated the action of the salivary glands and induced the formation of hormones which entered the blood and stimulated the flow of gastric juice. Any food taken with relish tended to promote the secretion of the exact sort of digestive juice most suited to that food. Water was the most important of all foods. All the foods used in infancy contained a large proportion of water, milk containing from 87 to 89 per cent. As salts were contained in all foods, it was unnecessary to consider them separately. The rôle of sodium chloride in edema was now well recognized, so that it should be withheld when one wished to get rid of that condition. But little peptone was absorbed in the stomach, though alcohol when dilute would increase the amount thus absorbed. When given in excess, or when not sufficiently subdivided, the peptones remained much longer in the stomach and when passed into the intestines they were prone to cause putrefaction. If the gastric juice was deficient, the same result was produced. The more rapid the process of peptone formation, the greater the amount absorbed high up in the tube. If the intestinal digestion was weak, the formation of peptones was slow and their absorption lessened. The proteins used in infancy, in the order of their digestibility, were breast milk, cow's milk, eggs, meat, and vegetable protein. The carbohydrates, if present in excess, might undergo fermentation, with the formation of lactic, acetic, succinic, and butyric acids, as well as gases. This acid formation checked the activity of the putrifying bacteria and so might be of use in the treatment of protein putrefaction, and the bacteria that throve in an alkaline medium. From carbohydrate fermentation there might result diarrhea with light and frothy stools. Of the carbohydrates in use in infant feeding the cane and malt sugars were especially prone to ferment. The chief advantages of the carbohydrates were that they were readily absorbed and were quickly available for energy in the liver and muscle cells as glycogen. Certain qualities of the fats made them difficult of utilization by sick infants. As the chief effect of fever was destruction of tissue and great loss of water it was evident that water was the food of first importance. In short attacks of fever it was the only necessary food. The addition of orange, lemon, or grape juice was an advantage in allaying thirst. The carbohydrates, being great protein sparers, should be given in as large quantities as could be well tolerated; fats should be given sparingly

as they were poorly digested in febrile conditions. Milk should be used in all cases that were not the result of milk indigestion or milk infection. Whole or skimmed milk should be preferred, not cream or top milk. In gastrointestinal disorders and diseases, if the child was breast fed, the intervals between the nursings should be lengthened and water given before the nursing. When an infant had no appetite, the intervals between feedings should be from three to four hours. If there was vomiting without fever, this was probably due to too large feedings and the child should be nursed for a shorter time and less frequently. Albumen water had, in his experience, resulted in intestinal putrefaction unless given in too small quantities to be of any nutritive value. In diarrheas, malted foods should be used with caution. Many infants were starved too long after summer diarrhea and colitis. The prolonged use of barley water was responsible for many of the cases of malnutrition seen at the end of summer. As soon as possible a gradual return should be made to milk and cereal gruels. Dr. La Fétra referred to feeding in typhoid fever, the exanthemata, pneumonia, diphtheria, pertussis, and tuberculosis. His paper was confined to a consideration of feeding in children under two years of age.

The Question of Clean Milk.—Dr. Walter Lester Carr said that the bacteria that occasioned changes in milk were of two kinds: (a) pathogenic or disease-producing, and (b) nonpathogenic or nondisease-producing. This latter class had a deleterious effect on the keeping quality of milk, but some varieties aided in its digestion, in fact, might be essential to it. With the pathogenic bacteria, there was no such question of value. Dr. Carr considered the three sources of infection, bacteria from the cow, bacteria from the milker and his utensils, and bacteria from the air. The great problem to be solved was to inhibit the growth of bacteria and yet not destroy the nutritive qualities of the milk. Milk with a rather high bacterial count, if kept below 50° F., could be shipped long distances and be wholesome food; while milk shipped at 70° F. would develop bacteria cultures that rendered it indigestible and dangerous. A milk kept at a temperature of 50° would show fewer bacteria after standing several hours; but the same milk, if kept at a temperature of 70° would show millions of bacteria after standing ten or twelve hours. A perusal of the requirements for the production of certified milk exacted by the Commission, acting under the authority of this Society, would convince one of the safety that users of this milk had. Thirty thousand bacteria per cubic centimeter were allowed; this number was infinitesimal compared to the number in many grades of family milk. The question of clean milk resolved itself into the oversight of dairies and milk so as to offer the safest substitute for mothers' milk, when this was not attainable. Certified milk was produced under the guarantee of this Society and was the safest milk that could be procured in New York City.

Dr. J. Milton Mabbott said he wished to add a word to the discussion as coming from one who was not a specialist in infant feeding. For three years he was resident physician of the Nursery and Child's Hospital and, therefore, he believed that he knew something about infant feeding. He still obtained good results in feeding children. One year ago last summer he was called to see a child brought back from the country. The mother was so sure there was no hope of recovery that she was praying that the child might be taken away as soon as possible out of its suffering. The baby was a premature child and the mother had been unable to nurse the infant. It weighed eight and a half pounds when seven months old. In such cases the speaker had previously used a peptogenic milk powder with occasional success. Milk modified by means of this powder was tried in this instance and the baby thrived. When one year old it weighed nineteen pounds, nearly the normal weight for a baby at that age. Dr. Chittenden of Yale University had also recommended this powder, stating that it enabled us to prepare a food closely resembling human milk.

Dr. Charles Gilmore Kerley said that America had been accused of being a great admirer of things that were made on the other side because they were supposed to have more value than similar things in this country. During the past summer he had had the opportunity to see a good deal of the medical work as it was done on the other side, and he wished to state briefly for the enlightenment of those present that in no country did he believe could such admirable papers be heard as they had just listened to on the subject of the nutrition of the young. Dr. Koplik's conclusions were at variance with the aim and object of the German pediatrists in relation to infant feeding; that was, following some set scheme, as suggested by Dr. Mabbott; this certainly was irrational in infant feeding. Dr. Koplik had referred to buttermilk; this was not used at the present time very much abroad nor did they use as high a percentage of fat as did Americans. They used skimmed milk. He observed that proteins were not used so much; they did not use fat so much, but to get what calories they desired they used an extra amount of sugar and carbohydrates. The point that Dr. Koplik brought out was one all should remember; there could be no one set scheme for infant feeding; whatever was done should be done as the result of careful study and according to individual characteristics.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, October 18, 1909.

The Vice-President, Dr. Ransford E. Van Gieson, in the Chair.

Report of the Delegates to the Recent International Medical Congress at Budapest.—By Drs. W. Freudenthal and Louis L. Seaman.

The Fundamental Functions of the Muscle Cells of the Cardiovascular System, with the Suggestion of a Classification of Arterial Disorders.—By Dr. Louis Faugeres Bishop. (See page 929.)

Dr. William H. Thomson said that when he was a student of medicine, the heart was apparently regarded as scarcely anything more than a living pump—an animated Davidson's syringe, and the most important feature regarding it was the condition of the valves. The presence of a murmur was the chief subject of attention, both as to diagnosis and to prognosis. After a time, however, experience showed that the state of the wall of the heart, the condition of the mural muscle, was of equal importance. This was a distinct advance, but it was not until the early sixties that the heart was first recognized as an essential part of the vascular system, and the influence that the vascular system, especially the arteries, had on the heart itself in the causation of heart disease. This led to an investigation of the causes of arterial lesions and changes in the arterial walls. Each of these advances in turn, however, great as they were, did not supersede those gained before in that now the importance attached to valvular disease is still taken into account as much as ever. Comparatively recently, the physiology and pathology of the rhythmical action of the heart had received much consideration, for it had been discovered that instead of the heart acting as a whole in its functions, as did the lungs, under certain morbid conditions, auricles and ventricles might contract and relax independent of one another. Study of the condition known as heart block, or Adams-Stokes disease, led in time to the discovery of that remarkable strand of muscular fibers called the bundle of His, and it was now known that

the contraction of the heart began in the auricle and spread, by means of this strand of fibers to the ventricle. If these fibers should be divided, then the ventricular beat no longer followed the auricular, and we had this condition of heart block, which was due to a defect in this bridge that conducted the auricular contraction over to the ventricle. Whether the rhythmical contraction of the heart was inherent to the heart muscles themselves or was due to the wonderfully rich nerve ganglia supplying that organ, or whether, as was most likely, it was due to a combination of both of these factors was a point that would have to be settled by further investigation. Discussing Dr. Bishop's paper from a therapeutic standpoint, Dr. Thomson said that in the treatment of cardiac conditions, one of the most frequent errors arose from the common conception that digitalis was a heart tonic. The action of digitalis on the heart was analogous to that of ergot on the uterus. Just as the effect of ergot was limited to a healthy uterus dilated by pregnancy, so that of digitalis was limited to a dilated heart without diseased walls. High tension pulse, Dr. Thomson said, should always be regarded as a dangerous symptom. It might be of acute onset, coming on without warning and to the great danger of the patient. As to the cause of arterial tension, it was inaccurate to say that kidney disease in itself caused it, because in some advanced cases of kidney disease, such as parenchymatous nephritis with dropsy, there might be no high tension. He ascribed high arterial tension to the presence of an excessive amount of suprarenal secretion in the blood, and he had found that even a very minute dose of adrenalin would raise the pulse to an uncomfortable degree in a healthy adult. One of the most valuable remedies we had in the treatment of cardiac disease was aconite, which had a slowing effect on the heart, regulating its action, and at the same time acting as an arterial dilator. It was especially indicated in the presence of high arterial tension, while opium was one of our best cardiac stimulants.

Dr. Richard Van Santvoord said the necessity of determining the condition of the peripheral circulation in cardiovascular diseases was generally recognized, and Dr. Bishop's reduction of the various factors which might be present to an exact classification was to be commended. Personally, he had usually considered the matter in a somewhat simpler way, namely, first, was there any abnormality in the tonus of the peripheral vessels, *i. e.* hypotonicity or hypertonicity of the vessels, and, second, what was the condition of the vessels with regard to elasticity? The causes of the loss of elasticity and the presence or not of muscular hypertrophy in the vessels had an obvious bearing on prognosis and treatment, and might be approximately determined as indicated by Dr. Bishop. The determining of the blood-pressure by one or other of the various forms of sphygmometers had become very general, but he had reason to believe that the necessity of interpreting its exact meaning was not so general. The instrument might be relied upon to give an approximately correct estimate of the systolic pressure. With the instrument that he was now using, that of Dr. Janeway, he had found it impossible to make any reliable estimate of the diastolic pressure. Even so high an authority as MacKenzie called in question the assertion that the point of maximum oscillation of the mercury in the manometer really indicated with any precision the diastolic pressure. Without such knowledge, the estimate of the systolic pressure, considered alone, was of little value. Dr. Van Santvoord said he had been accustomed for over twenty years to form an estimate of the state of the peripheral circulation from the sphygmographic tracing, and while he had been somewhat edified by the use of the sphygmometer, he found himself going back to the sphygmograph to learn what his readings of the other instrument meant. If Dr. Bishop's paper led to a wider appreciation of the necessity of a careful estimate of all the factors in abnormalities of the peripheral circulation in the diagnosis of cardiovascular diseases, it would serve a most useful purpose.

Dr. Edward E. Cornwall of Brooklyn agreed with Dr. Thomson that the value of digitalis as a heart remedy had been overestimated, and that we were now learning its proper use. Because it was valuable in reducing a dilated heart with relatively healthy muscles did not necessarily imply that it was indicated in all forms of heart disease. The speaker also referred to the value of strophanthus in small doses in certain forms of cardiac trouble, and of aconite to allay irritation and tension.

Dr. Leander H. Shearer said that, possibly excepting tuberculosis, no subject in internal medicine had received as much attention during the last few years as had cardiac disorders, and none had received as much benefit from physiological investigation as this particular branch. The speaker made a plea for the more general use of the instruments of precision that had been developed comparatively recently, not, however, to the exclusion of a proper consideration of the personal equation and the older well-known methods of diagnosis. Referring to the value of the venous pulse tracings, Dr. Shearer said that these had reached a point where they had become intensely practical and would aid very much in the prognosis of cardiac conditions. We knew that digitalis in certain forms of cardiac disease was harmful rather than beneficial, and with the venous pulse tracings it might be possible to differentiate certain cardiac conditions in which this drug should not be used. With further study of this phase of the subject, other tracings could probably be utilized in the same practical way. If necessary, cardiac patients could be referred for their tracings to men who were especially skilled in this particular line of work.

Dr. Thomas E. Satterthwaite said he believed that Dr. William H. Thomson was the first to imply that the two prevailing theories as to the agencies controlling cardiac contractions might now be regarded as established facts. While we knew that the embryonic heart beats before the development of the cardiac nerves has taken place, we also knew that mental activity quickened cardiac action. But there were other well known reasons in proof of both the myogenic and neurogenic theories. So it was that the muscular activities of the organ, so essential to life, were under the control of a dual set of agencies, and therefore the preservation of these all-important functions was doubly safe-guarded. Dr. Satterthwaite said he had of late years been greatly interested in the study of the clinical features of heart diseases as seen from the standpoint of physiology rather than from that of pathological anatomy. He was thoroughly in accord with the last speaker, in so far as he advocated a more extensive use of the polygraph. Of the five attributes of the heart as discovered by Gaskell, it accurately recorded three, namely, rhythmicity, contractility, and conductivity. The speaker referred to the excellent polygraphic machine completed by Dr. T. B. Barringer, Jr., which could show on the same polygram the respiratory curve, the arterial and venous pulses, and the movements of the cardiac apex, recorded in fractions of seconds by the time marker. Such an instrument not only insured positive diagnosis in many doubtful cases, but was useful in testing the comparative action of drugs. Certainly the profession should take more interest in this remarkable instrument. No large hospital should be without one, and a medical man skillful in manipulations and also in mechanics should be delegated to take the polygrams. Also, every well equipped hospital should have a physiology laboratory, in charge of a competent physiologist. In the matter of the classification of the cardiac diseases, the speaker said he was not disposed to advocate classifying them on an altogether physiological basis. The terms mitral stenosis, regurgitation, aortic and pulmonary valve

lesions, would remain in use for a long time, as they expressed conditions in a way that was not only satisfactory, but that at present could not be bettered. On the other hand, some morbid cardiac conditions were better stated in terms of physiology. Such were the arrhythmias. Certainly they could not be stated in terms of pathological anatomy. On the other hand, the present classification of vascular diseases was much more unsatisfactory, so that Dr. Bishop's effort for a better terminology in that direction was along the proper line.

College of Physicians of Philadelphia

At a stated meeting, held November 3, Dr. Jay F. Schamberg presented a communication entitled "An Epidemic of a Cutaneous Disease of Unusual Character Due to a Minute Mite in Straw Mattresses," and he accompanied his remarks with a lantern demonstration displaying the lesions of the affection and depicting the offending parasite, which was a parasite of an insect living on grain and straw, and it was as a rule not a direct parasite of man. Dr. John B. Deaver read a paper entitled "The Diagnosis and Surgical Treatment of Acute Pancreatitis, with the Report of Illustrative Cases." He dwelt upon the symptomatic features of the disease, considered its close relation to cholecystitis and cholelithiasis, and discussed the points of differential diagnosis. When the condition is well developed surgical treatment becomes necessary, although operation should be deferred until the more acute and violent symptoms have subsided. The diseased organ may be approached from in front through the peritoneal cavity or from the left loin, the latter approach the better, facilitating drainage and avoiding the risks of general peritonitis. Dr. James Tyson and Dr. Joseph Sailer presented a paper entitled "The Results of the Use of Beebe's Serum in the Treatment of Exophthalmic Goiter, with the Report of Three Cases." In none of the cases was any good accomplished, and it was suggested that various factors may be operative in different cases of the disease. Dr. S. Weir Mitchell spoke feelingly of the fact that this was to be the last meeting of the college in the old hall, where many professional friendships had been established and many important scientific communications had been made. While the college would enter its building with some debt on its shoulders, this would be provided for, and the college had every reason to be proud of the past and hopeful of the future. Dr. W. W. Keen moved a heartfelt vote of thanks to Dr. Mitchell for the large interest he had always exhibited in the welfare of the college and especially for the important part he had played in securing funds and promoting the plans for the erection of the new building, which was the finest of its kind in the country.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, State of Oregon.

Salem, July 6, 7, and 8, 1909.

ANATOMY.

1. Give the course and distribution of the trifacial nerve.
2. Name and give the origin of the arteries supplying the stomach, small intestine, large intestine.
3. Give the course and branches of distribution of the femoral artery.
4. Name the structures passing beneath Poupart's ligament.
5. What structures would be severed in an amputation at junction of the middle and upper thirds of the forearm?
6. Give the coverings of an incomplete oblique inguinal hernia.
7. Name and locate the various valves of the heart, and give the function of each set.
8. Name the tunics and the humors of the eye.

PATHOLOGY.

1. Give pathology of a carbuncle; and how does it differ from a furuncle?
2. Define phagocytosis, metastasis, leucocytosis.
3. Give the pathological anatomy and histology of acute parenchymatous or degenerative nephritis.
4. Give the pathology of atrophic portal cirrhosis ("gin-drinker's liver").

PHYSIOLOGY.

1. What is the function of the red corpuscles? State their number and what variation with altitude.
2. Give function of white corpuscles and state under what normal conditions leucocytosis occurs.
3. Describe the lymphatic system and state what factors control lymphatic circulation.
4. Give functions of auricles and ventricles of heart, and state what is meant by systole and diastole.
5. Name kinds and location of digestive ferments and state their action on foods in the small intestine.
6. How prove the spinal cord a center for reflexes?
7. Give name and state what kind of nerves the sixth and eleventh cranial nerves are. What does each supply?
8. What maintains the pitch of the voice?

HISTOLOGY.

1. Describe protoplasm. Does it possess structure?
2. Describe white fibrous tissue; also yellow elastic tissue, and state where found.
3. Describe in detail a lobule of the liver.
4. Where are nerve cells found?

GYNECOLOGY.

1. Name three leading causes of sterility, with treatment in each case.
2. Etiology, diagnosis, and treatment of retrodisplacements of the uterus.
3. Give five causes of pruritus of the vulva, with treatment in each case.
4. Give diagnosis, symptomatology, and treatment of septic abortion.
5. Name two common causes of dysmenorrhea, giving diagnosis and treatment.
6. Describe a miscarriage at five months, giving treatment to successful conclusions.
7. Diagnose and describe operation of salpingo-oophorectomy for adherent tubes and ovaries.
8. Describe operation for vaginal hysterectomy.

GENERAL DIAGNOSIS.

1. What diseases produce conditions of the skin which are of general diagnostic value?
2. What are the grades of temperature that come under observation in the sick?
3. Give the method for the detection of the tubercle bacillus in the sputum.
4. What is the diagnostic significance of dropsy?
5. Describe the characteristics and significance of the several kinds of pulse.
6. Give the symptoms of acute meningitis.
7. What are the diagnostic points in secondary syphilis?
8. What casts are frequently found in albuminous urine, and what do they denote?

NERVOUS DISEASES.

1. Give symptoms of tuberculous meningitis.
2. Define and give etiology of acute ascending paralysis.
3. What symptoms would you expect to find following rupture of a branch of the middle meningeal artery?
4. Give definition, prognosis, and treatment of puerperal insanity.

PRACTICE OF MEDICINE.

1. Give the etiology, pathology, common complications, and symptoms of typhoid fever.
2. Give the differential diagnosis of variola, varicella, scarlet fever, measles, and erysipelas.
3. State the etiology, pathology, diagnosis, and symptoms of croupous pneumonia.
4. Give the differential diagnosis of mitral regurgitation, aortic regurgitation, and aortic stenosis.
5. Give the pathology, etiology, and diagnosis of chronic interstitial nephritis.
6. Give the differential diagnosis of acute alcoholism, acute morphinism, and apoplexy.
7. State the pathology, etiology, symptoms, and treatment of ileocolitis of childhood.

8. State the pathology, etiology, and differential diagnosis of chronic gastric ulcer.

PRACTICE OF SURGERY.

1. Give the mechanism, pathology, symptoms, and treatment, and name the ligaments injured in backward dislocation of the hip-joint.

2. Describe amputation at middle third of arm, and name all tissues cut.

3. Give complete preparation of patient for abdominal section.

4. Describe the operation of posterior gastroenterostomy, and name the complications that may follow.

5. Give the anatomical relations, covering of sac, and detail of operation for femoral hernia.

6. State the etiology, pathology, diagnosis, symptoms, and treatment of osteomyelitis of the tibia.

7. Name the triangles of the neck; describe the relations and ligation of the common carotid artery.

8. State the etiology, pathology, symptoms, and treatment of pyelitis.

EYE AND EAR.

1. Give the etiology, diagnosis, symptoms, indications, and describe operation for mastoid abscess.

2. Give the differential diagnosis of gonorrheal conjunctivitis and blepharitis ciliaris.

3. Give the etiology, diagnosis, symptoms, and treatment of acute myringitis.

4. Give the treatment and your instructions to patient with marginal corneal ulcer.

5. Give the anatomy and appearance of a normal ear drum.

CHEMISTRY.

1. Write a comprehensive definition of chemistry in not more than sixty words.

2. Define briefly the following chemical terms and name a substance that is characteristic of each: Deliquescent; efflorescent; effervescent; fluorescent.

3. What do you consider the most practical chemical test for sugar, albumin, pus, blood, urea, in the urine?

4. Differentiate between empirical formula and graphic formula, giving as an example the formation of acetic acid.

5. Define "equation," and express the formation of mercurous chloride by chemical equation.

6. What do you understand by the term equivalent amounts in chemistry?

7. Define molecular weight, giving an example.

8. Define specific heat and name its unit.

MEDICAL JURISPRUDENCE.

1. What are the requisites of a hypothetical question, and under what circumstances may the opinion be given in evidence of (*a*) an expert witness, and (*b*) a non-expert witness?

2. What are the constituent elements of blood? How do you distinguish between the blood of mammalian vertebrates and that of oviparous vertebrates, and between the blood of different mammals? Name the different tests for blood stains, and give the principles upon which each test depends.

3. Define and describe the different kinds of wounds; how to determine whether a wound is ante- or post-mortem, and why, if at all, the size and shape of a wound does not always correspond to the size and shape of the instrument with which it was made.

4. Describe generally the proper method of conducting a post-mortem examination, giving details as to head, chest, abdomen, and spinal cord; state how you would test the lungs of a dead child to determine whether it had been born alive, and how you would recognize flotation caused by (*a*) artificial insufflation, (*b*) putrefaction, and (*c*) freezing.

OBSTETRICS.

1. What is the conjugate and transverse diameter of the inlet and outlet of the pelvis? Give its anatomical points of measurements.

2. What is the cause of rupture of the uterus, and under what circumstances does it occur?

3. Give your treatment for inevitable abortion.

4. Give your treatment for post-partum hemorrhage.

5. Give cause and treatment for transverse presentations.

6. Give cause, diagnosis, and treatment of puerperal eclampsia.

7. When would you use forceps, and how?

8. Give the anatomy of the uterus, and state what changes take place during gestation.

DISEASES OF CHILDREN.

1. Give the symptoms in morbus coxarius during the early stage of the disease. What other diseases might you differentiate it from?

2. Give the etiology and describe the pathology of hip-joint disease.

3. Give a clinical description of the various stages of rubeola.

4. Describe symptoms, prognosis, and treatment in ileocolic intussusception.

5. Atelectasis pulmonum; what is it? Note its symptoms and treatment.

6. Describe a process of peptonizing cow's milk, suitable for infant use.

7. Describe the principal striking clinical changes that take place in the skeleton in rhachitis.

8. From what other diseases would rhachitis have to be differentiated?

MATERIA MEDICA AND THERAPEUTICS.

1. Write an appropriate prescription in case of catarrhal jaundice; also two prescriptions to relieve cough in acute bronchitis.

2. Carbolic acid: origin, dose, and physiological action. Give appropriate treatment in case of poisoning.

3. What would be a suitable dietary in hyperchlorhydria, and give reason for same.

4. Apomorphine hydrochlorate: dose, physiological action, and therapeutic uses and indications.

5. Spiritus ætheris nitrosi: origin, dose, therapeutic uses, and common name.

6. What is a diaphoretic? Name four agents, and appropriate doses of each.

7. What do you understand (*a*) a cardiac tonic to be, and how does it act? (*b*) A cardiac stimulant, and how does it act? Give examples of each.

8. What are cathartics, and how do they act? Name five diseases or conditions in which the administration of a cathartic would be contraindicated.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF OREGON.

Salem, July 6, 7, and 8, 1909.

ANATOMY.

1. *Superficial origin:* From the side of the pons Varolii. *Deep* (sensory root), from the medulla and upper part of cord; (motor root) from floor of fourth ventricle and side of the aqueduct of Sylvius. *Exit:* The ophthalmic division, through the sphenoidal fissure; the superior maxillary division, through the foramen rotundum; the inferior maxillary division, through the foramen ovale. *Ophthalmic branch* distributed to conjunctiva, skin of upper eyelid, cornea, skin of forehead, and nose, lacrymal gland. *Superior maxillary*, to skin and conjunctiva of lower eyelid, nose, cheek, upper lip, upper teeth, and palate. *Inferior maxillary*, to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, and skin of lower part of face. Also to muscles as indicated under *Function*. It supplies sensation to all the parts mentioned above; but, in addition, Inferior maxillary supplies motion to the muscles of mastication, the mylohyoid, and anterior belly of the digastric.

2. The *stomach* is supplied by the gastric (from celiac axis), pyloric (from the hepatic), right gastroepiploic (from the gastroduodenal), left gastroepiploic and vasa brevia (from the splenic). The *duodenum*, by the pyloric and pancreaticoduodenal from the hepatic), the inferior pancreaticoduodenal (from the superior mesenteric). The *rest of the small intestine*, by branches of the superior mesenteric (from abdominal aorta). The *large intestine*, by the ileocolic, right colic, and middle colic (from the superior mesenteric); left colic, sigmoid, and superior hemorrhoidal (from inferior mesenteric). The *rectum*, by superior hemorrhoidal (from inferior mesenteric); middle hemorrhoidal (from internal iliac), and inferior hemorrhoidal (from internal pudic).

3. The *femoral artery* begins at Poupart's ligament; it is the continuation of the external iliac, and passes down the fore part and inner side of the thigh, to terminate at the opening in the adductor magnus at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. *Branches:* Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, muscular, anastomotica magna, and profunda femoris (with branches: external circumflex, internal circumflex, and three perforating).

4 These are (from without inward): External cutaneous nerve, iliacus, anterior crural nerve, psoas, femoral artery, femoral vein, femoral ring.

5. In amputation of forearm at junction of middle and

upper third, there will be severed: Skin, fascia, supinator longus, extensor carpi radialis, longior and brevior, extensor communis digitorum, extensor carpi ulnaris, supinator brevis, anconeus, pronator radii teres, flexor carpi radialis, palmaris longus, flexor sublimis digitorum, flexor carpi ulnaris, flexor profundus digitorum; arteries: anterior interosseous, radial, ulnar; veins: radial, interosseous, ulnar, median; nerves: posterior interosseous, radial, median, ulnar; bones: radius, ulna.

6. From without inward: Skin, superficial fascia, intercolumnar fascia, cremasteric fascia, infundibuliform fascia, subperitoneal areolar tissue, and peritoneum.

7. In the *right auricle* are the Eustachian and coronary valves; the former is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice; in the fetus it directs the blood from the inferior vena cava through the foramen ovale into the left auricle; the coronary valve prevents the regurgitation of blood into the coronary sinus during the auricular contraction. In the *right ventricle* are the tricuspid and semilunar valves; the former prevent the blood in the right ventricle from flowing back into the right auricle during ventricular systole; the latter guard the orifice of the pulmonary artery. In the *left ventricle* are the mitral and semilunar valves; the former acts similarly to the tricuspid; the latter guard the orifice of the aorta. Aortic valves, behind the third intercostal space, close to the left side of the sternum. Pulmonary valves, in front of the aortic, behind the junction of the third rib, on the left side, with the sternum. Tricuspid valves, behind the middle of the sternum, about the level of the fourth costal cartilage. Mitral valves, behind the third intercostal space, about one inch to the left of the sternum.

8. *Tunics:*. (1) Sclerotic and cornea; (2) choroid, ciliary body, and iris; (3) the retina. *Humors:* (1) Aqueous humor; (2) vitreous body; (3) crystalline lens.

PATHOLOGY.

1. A *carbuncle* is due to infection with a pus organism, which causes an acute inflammatory exudation. The dense fibrous tissue under the skin does not yield, and the compression strangles the vessels. Septic gangrene results from these causes. Later, the living tissues suppurate around the septic slough and form pus. The pus breaks through the overlying skin in one or two places and the slough is discharged, the cavity being filled up by granulation and cicatrization. A *furuncle* opens by a single opening, instead of several, and is frequently multiple.

2. *Phagocytosis* is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria. *Metastasis* is the transfer of a morbid process from one part of the body to another not directly continuous with it. *Leucocytosis* is an increase in the number of white corpuscles in the peripheral blood.

3. The epithelium of the tubules, especially in the convoluted portions, is swollen, cloudy, and considerably desquamated. Leucocytes and some red corpuscles are found within the tubules and the Malpighian capsule. The kidney is enlarged, somewhat swollen, and rather pale in color. The changes are most marked in the cortex, which is thicker than normal. The capsule strips easily.

4. The liver is shrunken and indurated, rough, and of a pale or yellow color; a growth of new connective tissue is disposed in broad bands which run in various directions, and by their contraction divide the liver into numerous irregular lobes. Many acini may be affected at one time. The capsule may be thickened, or adherent to the diaphragm. Jaundice is slight, and comes on late; ascites is pronounced and may occur early.

PHYSIOLOGY.

1. The function of the red corpuscles is to supply the tissues with oxygen. There are about 4,500,000 to 5,000,000 to the cubic millimeter of blood. Altitude causes an increase in their number.

2. The white corpuscles serve as a protection against pathogenic microorganisms; they take some part in the process of the coagulation of the blood; they aid in the absorption of fats and peptones from the intestine, and they help to maintain the proper proteid content of the blood plasma. Leucocytosis occurs normally during digestion, after exercise, during pregnancy, and the puerperium, in the newborn, and just before death.

3. The lymphatic system consists of: lymphatic glands, lymph vessels, perivascular lymph spaces, the lymph canalicular system, the pericardial, pleural, peritoneal, and synovial cavities, and the lacteals. The forces concerned in the circulation of the lymph are: The pressure of the blood in the blood-vessels: thoracic aspiration; contractions of the voluntary muscles; contractions of the intestine; the action of the valves in the lacteals and lymphatics.

4. The function of the auricles is to receive the blood from the body and from the lungs. That of the ventricles is to send the blood to all parts of the body and to the lungs. Systole is that period when the ventricles (or auricles) are contracting. Diastole is that period when the ventricles (or auricles) are not contracting, but are at rest, and receiving blood.

5.

DIGESTIVE FERMENTS	ORIGIN	FUNCTIONS
Ptyalin.	Saliva.	Changes starches into dextrin and sugar.
Pepsin.	Gastric juice.	Changes proteids into proteoses and peptones in an acid medium.
A curdling ferment.	Gastric juice.	Curdles the casein of milk.
Trypsin.	Pancreatic juice.	Changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin in an alkaline medium.
Amylopsin.	Pancreatic juice.	Converts starches into maltose.
Steapsin.	Pancreatic juice.	Emulsifies and saponifies fats.
A curdling ferment.	Pancreatic juice.	Curdles the casein of milk.
Invertin.	Succus entericus.	Converts maltose into glucose.

6. The fact that parturition can occur in a woman when under the influence of an anesthetic shows that the center of the movement of the uterus is in the spinal cord, and not in the brain.

7. The sixth cranial nerve is the abducens; it is the motor nerve to the external rectus muscle of the eye. The eleventh cranial nerve is the spinal accessory; it is a motor nerve.

8. The pitch of the voice depends upon the number of vibrations and the length of the vocal cords during a given time, and is maintained by the state of tension of the vocal cords.

HISTOLOGY.

1. Protoplasm is an unstable albuminoid substance, viscid, and generally colorless. It consists of a fibrous network and a more fluid portion, which fills the meshes of the former. Views differ as to the structure of protoplasm.

2. *White fibrous tissue* is made of glistening fibers covered with loose flocculent tissue. It has no elasticity, very little extensibility, but very great strength. In ligament and tendons the bundles are parallel with each other; in membranes, they intersect each other at various planes. The cells are situated on the surface of groups of bundles, are arranged in single file and joined by cement substance. It is found in ligaments, tendons, muscular fascia, periosteum, perichondrium, pericardium, dura mater, sclerotic coat of eye, tunica albuginea of testis, epineurium. *Yellow elastic tissue* is of yellowish color, is very elastic, and has but little of the fibrous variety. It consists of fibers with curling ends and of well-defined outline; these are larger than the white fibrous kind. It is found in Ligamenta subflava, vocal cords, trachea, bronchi, larynx, blood-vessels, thyrohyoid, cricothyroid, and stylohyoid ligaments.

3. A lobule of the liver is about 1-20 to 1-12 inch in diameter. It has a darkish red center and a lighter circumference. The center is occupied by an intralobular vein which collects the blood from the capillaries of the lobule, and flows into the sublobular vein, which latter opens into the hepatic vein. Around the lobules are the interlobular veins; these are branches of the portal system; capillaries passing from the circumference to the center of the lobule connect the interlobular and intralobular veins. Between the network of capillaries in the lobule the hepatic cells are packed.

4. In the gray matter of the brain and spinal cord sympathetic ganglia, ganglia on cerebrospinal nerves, and in the organs of special sense.

GYNECOLOGY.

1. (1) Absence of, or errors in development of, any part of the genital tract. *Treatment:* Little or nothing can be done: atresia of the crevix can be treated by dila-

tation. (2) Malpositions of the uterus. *Treatment:* Replacement. (3) Membranous dysmenorrhea. *Treatment:* Dilatation of cervix and curettage.

2. Retroflexion. *Etiology:* Tight lacing and tight clothing; congenital conditions; pressure by tumors; metritis and parametritis with adhesions; atonic conditions of the uterus following labor; and the conditions that cause retroversion. *Diagnosis:* The cervix is low in the pelvis; the fundus is in the cul de sac of Douglas; bimanual examination will show the flexion. *Treatment:* If there are no adhesions, the flexion should be corrected by digital manipulation and a pessary introduced; hysteropexy may be necessary.

Retroversion. *Etiology:* Relaxation of uterine ligaments; increased weight of fundus; subinvolution; ovarian or other tumor pressing on front of uterus; distended bladder; peritonitis or cystitis; prolonged dorsal decubitus and tight bandaging in the puerperium. *Diagnosis:* Conjoined manipulation will show the cervix displaced toward the pubes, and the body of the uterus in the hollow of the sacrum. *Treatment:* Remove the cause, if possible; replace the uterus and keep it in position by pessaries, tampons, and knee-chest position; pelvic massage and vaginal douches; proper hygiene, particular attention being paid to the bowels, clothing, and exercise. *Curative treatment:* The choice lies between ventral suspension of the uterus and shortening of the round ligament.

3. Parasites, diseases of the vulva, irritating discharges, diabetic urine; it may also be of nervous origin, or idiopathic. *Treatment* consists in removing the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of bichloride of mercury, 1:2,000; or carbolic acid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

4. *Septic abortion* shows chill, followed by high temperature and rapid pulse; lochia is first diminished or suppressed, later returns and is dark, purulent, and has an offensive odor; uterine pains, suppression of urine, exhaustion, and typhoid state are present. The symptoms usually come on in from one day to a week after the operation. The diagnosis is made by the history of the case and the symptoms. *Treatment:* Uterine douche of corrosive sublimate (1:2,000), two or three times at intervals of eight hours, followed by hot normal salt solution. If there is no immediate improvement, curettage is indicated. If the symptoms are severe, curettage should be done at once, and the douching take place subsequently. The vagina is douched twice a day with corrosive sublimate and saline solutions, as above. If the symptoms do not subside, the intrauterine douche or curettage may be repeated.

5. *Dysmenorrhea* may be due to: (1) Anteflexion of uterus; for treatment, see above, No. 2. (2) Tumors, such as fibroids; treatment consists in removal of the tumor.

6. In a *miscarriage at five months* there will be profuse hemorrhage; severe cramp-like pains, like labor pains; rupture of membranes, and escape of liquor amnii, and the fetus will be expelled. There will be a history of pregnancy and the signs of the same. The patient should be put to bed and the case in general be managed the same as if it had been a labor at full term.

7. *Salpingo-oophoritis.* When adhesions bind together the tube, ovary, and adjacent peritoneum, these parts form a lump, the component parts of which cannot be distinguished without opening the abdomen. All the symptoms may be caused by other diseases; sometimes there are no symptoms, but this is exceptional. There is pain, referred principally to the lower abdomen, lessened slightly by lying down; it is aggravated by defecation, exertion, and sexual intercourse. Menstruation is generally profuse, irregular, and painful. Micturition is frequent and painful. The general health is poor, and anorexia, nausea, insomnia, and neurasthenia may be present. If both sides are affected, sterility results. The uterus alone can be felt bimanually, the other parts constituting a thickened mass on either side or behind the uterus.

Operation of salpingo-oophorectomy: "(1) Perform a median abdominal section—control hemorrhage—and retract lips of abdominal wound. (2) Pass the first and second fingers into the wound, with the back of the hand to the abdomen; follow down the under surface of the abdominal parietes to the symphysis, thence down on to the bladder and uterus, and thence out laterally over the superior cornu of the uterus, with the palm of the hand still downward, to and along the broad ligament, along the posterior superior aspect of which the Fallopian tube is found, and, just posterior to the tube, the ovary. These structures are drawn toward the median line into an accessible position in the abdominal wound. (3) The ovarian artery and veins are first tied, with silk, the ligature being carried, upon a laterally curved aneurysm needle, through the clear space of the broad ligament and tied over the top of the infundibulopelvic ligament, outside of the fimbriated end of the Fallopian tube, and close to the brim of the pelvis. (4) The uteroovarian ligament, lying behind the Fallopian tube, is ligated with chromic gut, rather nearer the uterus, carried upon a laterally curved aneurysm needle. (5) The inner end of the Fallopian tube and the upper free part of the broad ligament are ligated with silk near the horn of the uterus—which ligature also controls the branches from the uterine artery. (6) The structures are now removed by cutting through the broad ligament well within the outer ligature of the ovarian vessels—and cutting through the Fallopian tube and ovarian ligament well to the outer side of their ligatures—and carrying the incision through the broad ligament well below the hilum of the ovary. Any doubtful ligature is strengthened, and any bleeding point is surrounded by an additional gut ligature. (7) The edges of the anterior and posterior layers of the broad ligament, left by the removal of the above structures, are sutured together with gut. The patient is lowered to the horizontal position and the intestines and omentum are replaced. (8) The abdomen is closed, as after median abdominal section."—(Bickham's *Operative Surgery.*)

8. *Vaginal hysterectomy:* "The patient is catheterized and placed in the lithotomy position and the external genitals are thoroughly disinfected. The vagina is held open by broad retractors and the uterus is pulled down by volsella forceps grasping the cervix, while the adjoining mucous membrane is cut well clear of the disease by blunt-pointed scissors. Keeping close to the uterus, the dissection is continued on its anterior and posterior surface by the tip of the finger and short snips of the scissors, but at the sides, after division of the mucous membrane, the cellular tissue is simply pushed up as high as possible, or till the pulsations of the uterine artery are felt. The finger is finally thrust through the uterovesical fold of peritoneum, and after cleansing the vagina flat sponges are poked in around the uterus. Douglas's pouch is entered in the same manner, hemorrhage from the vaginal wound being controlled by a few catgut sutures through its cut edges, and then the finger is hooked over the fundus, pulling it down into the posterior opening and thus bringing within reach the upper border of the broad ligaments, which are seized by long-bladed clamps and divided on the uterine side. Other clamps are placed on the remaining tissues close to the uterus, which is then excised.—(Stimson's *Operative Surgery.*)

GENERAL DIAGNOSIS.

1. Syphilis, erysipelas, measles, scarlet fever, smallpox, chickenpox, typhoid fever, typhus fever, yellow fever, jaundice, purpura hæmorrhagica, Addison's disease, argyria, chlorosis, anemia, various drug eruptions, and skin diseases.

2. Subnormal temperature, below 97.50; normal, 97.5 to 99.5; subfebrile, 99.5 to 100.5; slight fever, 100.5 to 101.5; moderate fever, 101.5 to 103; high fever, 103 to 105, hyperpyrexia, above 106.

3. The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

4. *Dropsy may indicate* obstruction of the portal circulation, cardiac or pulmonary diseases, disease of the peritoneum, diseases of the kidneys, anemia, debility, exposure to cold or wet, cancer, syphilis.

5. (1) *Frequent pulse:* In fevers, exophthalmic goiter, early phthisis, heart disease, anemia, chlorosis, locomotor ataxia, abuse of alcohol, tea, coffee. (2) *Slow pulse:* In cardiac disease, cerebral tumor or hemorrhage, meningitis, myxedema, epilepsy, some poisons, digestive disorders. (3) *Intermittent pulse:* In cardiac disease, fevers, poisons, neurasthenia, cerebral troubles, digestive disturbances. (4) *High tension pulse:* In arteriosclerosis, gout, diabetes, contracted kidney. (5) *Low tension pulse:* In fevers, anemia.

6. Sudden onset: very severe pains in neck, back of

head and spine; head is strongly retracted, causing opisthotonos; Kernig's sign (inability to straighten the leg when the patient is lying down and the thigh flexed at right angle to the body); delirium may be present; and in the cerebrospinal fluid there may be found the *Diplococcus intracellularis* of Weichselbaum, or the *Streptococcus pyogenes*.

7. The skin eruptions, or syphilides (characterized by not itching, by being of a coppery or raw ham color; generally symmetrical; painless; by polymorphism); mucous patches; sore throat; condylomata; alopecia; iritis; periostitis.

8. *Hyaline* casts occur in all forms of nephritis, in congestion of the kidneys, in jaundice; *waxy* casts, in chronic parenchymatous nephritis; *epithelial* casts, in acute parenchymatous nephritis; *granular* casts, in chronic nephritis and in acute nephritis; *fatty* casts, in chronic parenchymatous nephritis; *blood* casts, in hemorrhagic nephritis; *pus* and *bacterial* casts, in suppurative nephritis.

NERVOUS DISEASES.

1. In addition to the symptom of ordinary meningitis (see above, DIAGNOSIS, No. 6), there is frequently tuberculosis in other parts of the body. The onset is sudden, and there is the hydrocephalic cry. The pulse is first rapid, then slow and irregular, the respirations irregular and sighing, and the pupils are generally contracted. In the second stage there are constipation, retraction of the abdomen, stupor, and irregular pupils. The temperature ranges from 101° to 103° F. Later there may be various paralyses, diarrhea may replace constipation, and the symptoms become typhoid in character.

2. *Acute ascending paralysis* is an acute disease characterized by a motor paralysis beginning in the feet and legs, rapidly extending to the trunk and arms, and finally involving the muscles of respiration and deglutition. The cause is unknown. It has been asserted to be a peripheral neuritis, of infectious origin, or a functional disorder whose anatomical basis is unknown.

3. A period of unconsciousness followed by hemiplegia and convulsions, pupils dilated on side of lesion, stupor or coma, slow and labored breathing, slow and full pulse, vomiting, aphasia, hemianesthesia, loss of control of sphincters, increased reflexes.

4. *Puerperal insanity* is insanity following childbirth. Patients recover, but the prognosis for life is better than that for recovery. Treatment should be directed to the patient's general condition; food, rest, sleep, and strengthening medicines are particularly indicated. Good nursing, constant watchfulness, and tact are essential. The bowels and bladder must be regularly evacuated, and care should be taken to prevent bedsores.

PRACTICE OF MEDICINE.

1. TYPHOID FEVER. The bacillus of Eberth is the pathogenic microorganism of the disease; it is conveyed by contaminated food or water. In the first stage Peyer's patches become swollen, hyperemic, and reddened; a few days later they appear as whitish or gray elevations, and the hyperemia has disappeared; the surface of the patch is smooth and its edge is sharply defined; after the first week necrosis may occur; the necrotic portion falls off, leaving an irregular ulcer with undermined edges. These ulcers are elongated, with the long axis parallel with that of the intestine; they may heal or go on to perforation. The spleen becomes congested and enlarged, is liable to infarction; the liver is enlarged; the heart becomes soft and flabby. *Common complications:* Hemorrhage or perforation of bowel, peritonitis, thrombosis, meningitis, pneumonia. *Symptoms:* Insidious onset, weakness, headache, epistaxis, vague pains. The temperature rises gradually, about 2° in the evening, and falling 1° in the morning. Diarrhea, tenderness in the right iliac fossa, enlarged spleen, and a characteristic rash which appears from seventh to twelfth day. During the second week the temperature remains at a uniform level; typhoid state and delirium may be present. The pulse becomes rapid, weak, and dicrotic; the heart sounds are feeble; the tongue is coated, fissured, and tremulous; sordes appear on the teeth; the abdomen is distended; the stools are yellowish and offensive (said to be like pea soup); the Widal reaction may be positive. In the fourth week the temperature becomes normal.

2. *Variola:* The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin. *Varicella:* The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent. *Measles:* Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small, dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present. *Erysipelas* is characterized by: A rise of temperature; a tendency to spread; the skin is swollen and the affected part has a well-defined border and raised margins; the rash is local, not punctate, but bullous; there are pain, considerable constitutional disturbance, and a possibility of infection.

3. See French's Practice of Medicine (1907), pages 151 *et seq.*; or Osler's Practice of Medicine (1909), pages 164 *et seq.*

4. In *mitral regurgitation* there is a systolic murmur, heard loudest at the apex, transmitted toward the left axilla, and often heard at the angle of the left scapula. The heart is enlarged. In *aortic regurgitation* there is a diastolic murmur, heard loudest at the second interspace, transmitted down the sternum. The left ventricle is hypertrophied. There will also be present Corrigan's pulse, and pulsating arteries in the neck. In *aortic stenosis:* A systolic murmur heard over the aortic area, transmitted into the carotids, and usually accompanied by a loud first sound. Hypertrophy of the left ventricle, increased area of cardiac dullness, apex beat is displaced downward and to the left, the pulse is generally small and infrequent.

5. See French's Practice of Medicine (1907), pages 901 *et seq.*; or Osler's Practice of Medicine (1909), pages 694 *et seq.*

6. In *acute alcoholism* the coma is not usually absolute; there may be an odor of alcohol on the breath, the patient can generally be aroused by shouting in his ear; there is no paralysis; the pupils are normal or dilated; respiration is practically normal; the pulse is first rapid and later feeble, and the skin cool. In *acute morphinism* the pupils are contracted, there is no sign of paralysis; both respirations and pulse are slow and full. In *apoplexy* there is generally paralysis of the head and upper limbs, and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

7. See French's Practice of Medicine (1907), pages 771 *et seq.*; or Osler's Practice of Medicine (1909), pages 508 *et seq.*

8. See French's Practice of Medicine (1907), pages 745 *et seq.*; or Osler's Practice of Medicine (1909), pages 470 *et seq.*

PRACTICE OF SURGERY.

1. *Backward dislocation of the hip* is of two kinds: (1) On to the dorsum ilii; (2) on to the sciatic notch. *Dorsal dislocation:* Head of femur lies on the dorsum ilii, and can be felt in the buttock. The obturator internus is ruptured in most cases. The short rotator muscles are lacerated. The trochanter lies well above Nelaton's line and approximated to the anterior superior iliac spine. The leg is shortened two to three inches. The iliotibial band is relaxed. The leg is flexed, adducted, and inverted. The femur crosses the lower third of the opposite thigh. The toe rests on the opposite instep. A hollow exists in Scarpa's triangle. *Sciatic dislocation:* Similar to the above, except in the following:—The obturator internus tendon is intact and lies over the neck of the femur, holding it down in the sciatic notch. Shortening amounts only to one inch or less. The axis of the femur crosses the opposite knee. The great toe rests on the dorsum of the opposite great toe. *Treatment:* In posterior luxation of the hip joint the patient should be placed on a mattress on the floor, and then be anesthetized. The leg is then to be flexed on the thigh, and the thigh flexed on the abdomen; adduction is to be increased so that the knee is beyond the middle line of the body; then abduct, freely circumduct outward, and finally extent the limb so that it is parallel

with the other. *Ligaments injured:* Ligamentum teres and capsular ligament.

2. For the technique see any textbook on Operative Surgery. In amputation through the middle of the arm the following parts are divided: Skin; fascia; biceps, triceps, and brachialis anticus muscles; brachial, superior profunda, and inferior profunda arteries; brachial, basilic, and cephalic veins; median, ulnar, internal cutaneous, musculospiral, and musculocutaneous nerves; and humerus.

3. See Rose and Carless' Surgery (1902), page 966; or DaCosta's Surgery (1903), page 48.

4. See Rose and Carless' Surgery (1902), page 918; or DaCosta's Surgery (1903), page 797.

5. Femoral hernia is always *acquired*, and has a sac. Its course is first vertical, then forward, then upward over Poupart's ligament. Its coverings, from without inward, are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum. The neck of the hernia is situated at the femoral ring; to its outer side lies the femoral vein, and to its inner side is Gimbernat's ligament; in front of it is Poupart's ligament, and behind it are the pubis, the pectineus, and the pubic portion of the fascia lata. In the immediate neighborhood of the femoral ring are: Anteriorly, the communicating branch between the deep epigastric and the obturator arteries; externally, the femoral vein and deep epigastric vessels; superiorly, the spermatic cord or round ligament) and the deep epigastric vessels.

For details of operation see Rose and Carless' Surgery (1903), page 991; or DaCosta's Surgery (1903), page 841.

6. *Etiology:* It is *caused* by infection, the bacteria gaining entrance either through a wound or by extension from neighboring tissues, or they may be brought by the blood. *Pathological Changes:* "The area of the medulla affected becomes hyperemic; exudation occurs in the cancellous spaces, Haversian canals, and under the periosteum. Pus soon forms in these three situations. If the disease begins in the superficial part of the bone, the pus may only be subperiosteal, the deeper part of the bone escaping, though large areas of the superficial portion may die from the combined action of (1) stripping up of the periosteum by the pus, (2) strangulation of the vessels in the bone by the pressure of the exudation, and (3) the toxic action of the bacterial products. . . . When the disease begins in the deeper layers of the bone, the pus may reach the periosteum, or extend along the medullary cavity, so that the veins become filled with septic thrombus, which may be disintegrated and carried off as septic emboli (pyemia). There is profound toxemia, and necrosis of the whole diaphysis may occur. . . . If the infection is mild, a chronic abscess may be formed in the cancellous tissue. The usual course of an acute case, if a patient survives, is that there is some necrosis of the shaft of the bone. The abscess bursts externally, and there are numerous openings in the skin leading through openings (cloacæ) in the periosteum and involucrum down to the sequestrum. The sequestrum becomes loose in six weeks to six months. *Symptoms:* Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; scepticemia or pyemia, may be present. It is to be *diagnosed* from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tubular arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis*, in which the bone and periosteum are not affected, and in which there is always a wound. *Treatment:* Immediate incision through the periosteum; the surface of the bone must be opened, pus evacuated, and drainage instituted; irrigation with hot bichloride solution and packing with gauze. The medulla of the bone must be freely exposed, and any suppurating material removed. Constitutional treatment and rest are indicated.

7. The triangles of the neck are: (1) Anterior (containing the inferior carotid, superior carotid, and submaxillary triangles); (2) Posterior (containing the occipital and subclavian triangles). For the relations of the common carotid see Cunningham's Anatomy (1905), page 802; or Gray's Anatomy (1908), page 600; for the ligations, see Rose and Carless' Surgery (1902), page 283; or DaCosta's Surgery (1903), page 348.

8. *Pyelitis* is due to: (1) calculi; (2) tuberculous disease; (3) extension of sepsis from the bladder and urethra; (4) sometimes movable kidney; (5) the ingestion of cantharides or turpentine; (6) a pyemic embolus.

The lining membrane is red and swollen, and exudes muco-pus or pus. A certain amount of hydronephrosis occurs from the blockage produced by the swelling. When pyogenic organisms are present, the kidney substance may be invaded (pyelonephritis). Perinephric suppuration may follow from extension.

The *Symptoms* are pain and tenderness over the kidney, frequency of micturition, and pus in *acid* urine, unless there is cystitis as well, when the urine is alkaline. The pyuria is intermittent when the ureter is occasionally blocked.

Treatment: The cause is removed if possible. When pyelitis is due to extension from the bladder, the latter must be attended to.

EYE AND EAR

1. Mastoid abscess. *Etiology:* Infection from nasopharynx or ear, purulent otitis, exanthemata, grippe, inflammation of middle ear. *Symptoms:* Tenderness, pain, swelling and redness over the mastoid; bulging of the superior and posterior parts of the auditory canal; temperature variable, from normal up to about 104° F. *Treatment:* Hot water, or cold water, or ice; leeches; purgatives; light diet; acetanilid; incision, or mastoid operation. *Operation:* A semicircular incision of the soft parts is carried from a point about one-half inch above the attachment of the auricle, backward and downward, keeping parallel to the auricular attachment and terminating at the tip of the mastoid. The periosteum is now elevated or dissected from the bone and the osseous structure thoroughly exposed by means of retractors, which are held by an assistant, the auricle being pulled forward so as to lie upon the side of the head. The hemorrhage is controlled by the use of hot sponges and artery forceps. The surface of the mastoid is thoroughly examined for areas of necrosis or the existence of a fistulous opening, especially if a fluctuating swelling obtains previous to the operation. If these exist, the openings are enlarged by means of a gouge or a chisel and mallet, and followed inward to their origin. Should the surface present a healthy appearance, the primary opening of the mastoid is made into the antrum by means of the chisel, the point of entrance being effected just below the line of the superior wall of the meatus and about one-quarter of an inch backward from the posterior wall or anterior edge of the mastoid bone. When the antrum has been exposed, the cortex of the mastoid is chiselled away from this point downward toward the tip until a sufficient amount has been removed to expose all parts of the mastoid process. The cells are now all broken down, and every vestige of a necrotic or granulating area is completely eradicated. A free communication of the antrum with the tympanum should be established, which may be proved by syringing an antiseptic solution into the antrum, when it will escape from the external auditory meatus through a previous perforation of the drum head. The cavity of the mastoid is packed with sterile gauze, and the flaps of overlying tissue allowed to regain their former position, when a gap remains between their edges, through which the dressings may be changed (From Alling and Griffin's *Epitome on Eye and Ear*).

2. In *gonorrheal conjunctivitis:* The conjunctiva and the lids are red and swollen; the secretion contains pus, in which the gonococcus may be found; the eye is tender and painful; the cornea may ulcerate; there is generally a history of gonorrheal infection.

In *blepharitis:* The margins of the lids are swollen and reddened; the lashes fall out, and may or may not grow again; the lids are glued together by yellowish crusts; under these crusts are ulcers which bleed readily; itching, soreness, epiphora, and sensitiveness to light are noticed; there may be eczema of the eyelids.

3. Myringitis. *Etiology:* Trauma; extension of inflammation from middle ear or nasopharynx; exposure. *Symptoms and Diagnosis:* Pain, fulness; tinnitus; slight disturbance of hearing; if abscess forms the pain is great. *Treatment:* Irrigate auditory canal with a warm alkaline antiseptic solution, or with a solution of corrosive sublimate 1:5,000, and insert a pledget of cotton in the meatus; vesicles should be opened.

4. In *corneal ulcer* the patient's general condition must be kept up with proper food, hygiene, fresh air, tonics, and attention to bowels, etc. Atropine, antiseptic applications, bandages, hot compresses, paracentesis of the cornea, or Saemisch's operation (division of the ulcer) are indicated.

5. The *membrana tympani* separates the external auditory meatus from the tympanic cavity. It is a thin, semitransparent, oval membrane, broader above than below, concave outwards, and lying obliquely downwards and inwards. The most depressed part of the cavity is called the umbo. Its outer surface is continuous with that of

the meatus; its inner covering is reflected from the lining of the tympanum; between the two is a fibrous membrane. There can be seen a ridge formed by the handle of the malleus, and also a bright triangular reflection of light at the anterior and lower part, running from the umbo towards the periphery. This is called the "pyramid of light." It is lustrous, and of a pearly color.

CHEMISTRY.

1. *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing such changes.

2. A *deliquescent* substance is one that absorbs sufficient moisture from the air to form a solution; example, calcium chloride. An *efflorescent* substance loses its water of crystallization on exposure to the air; example, sodium carbonate. An *effervescent* substance, when placed in a liquid, causes sudden liberation of a gas; example, seidlitz powder. A *fluorescent* substance possesses the quality of lowering the refrangibility of light rays so as to convert the invisible ultraviolet rays into visible violet rays; example, quinine.

3. *Sugar:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Albumin: The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Pus in the urine: Acidify the urine with acetic acid, then filter it, and treat the filter with a few drops of freshly prepared tincture of guaiacum; a deep blue color denotes the presence of pus.

Blood: To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

Urea: "The specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ. One volume of the urine is than mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted: every degree of loss in specific gravity indicates 0.7791 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature; and that of the mixture only when the evolution of gas has ceased entirely." (Witthaus' *Manual of Chemistry.*)

4. The *empirical formula* shows only the composition, that is, the number and kinds of atoms that are present in a molecule. The graphic formula shows both the composition and the constitution, that is, the relation that the atoms bear to each other within the molecule. The empirical formula for acetic acid is $C_2H_4O_2$; the *graphic* formula is $CH_3.COOH$.

5. An *equation* is an expression, by means of symbols, numbers and signs, of a chemical action. $HgSO_4 + Hg + 2NaCl = Na_2SO_4 + Hg_2Cl_2$.

6. The *equivalent weight* is the weight of an atom or radicle which can replace or combine with one part by weight of hydrogen or chlorine. It is the atomic weight of the element divided by its valence.

7. *Molecular weight* is the weight of a molecule of a substance as compared with the weight of an atom of hydrogen. It may also be said to be the sum of the weights of the atoms composing the molecule. Thus, the molecular weight of sulphuric acid, H_2SO_4, is $(2 + 32 + 64)$, that is 98; or 98 times the weight of an atom of hydrogen.

8. *Specific heat* is the amount of heat required to raise the temperature of a substance a given number of degrees. The unit of specific heat is the Calorie, which is the amount of heat required to raise the temperature of one gram of water from 4° to 5° C.

MEDICAL JURISPRUDENCE.

1. *The requisites of a hypothetical question,* are: (1) It should embrace *substantially* all the evidence in the case relating to the subject. (2) It need not embrace all the evidence on the subject. (3) Each side may submit a different hypothetical question, based on the hypothesis of the facts which it considers proved. (4) It should be sufficiently explicit to warrant the formation of an opinion. (5) It should contain no irrelevant matter.

An *expert* witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically,* this can only be done by one perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness. A *non-expert* witness testifies only the *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

2. The constituent elements of blood, are: Red corpuscles, white corpuscles, platelets, and serum. In mammals as a rule, the red corpuscles are circular and nonnucleated; in oviparous vertebrates, as a rule, the red corpuscles are oval and nucleated. The blood of different mammals is differentiated by the measurement of the red corpuscle. *To identify blood stains:* (1) Some of the material from the suspected stain is thoroughly mixed with a few drops of a saturated solution of sodium chloride, and then allowed to evaporate to dryness on a slide covered with a cover-glass. Now add a drop of glacial acetic acid to the slide, and allow it to enter under the cover slip; then apply gentle warmth. If the suspected stain is *blood,* crystals of hemin will form later, and can be seen under the microscope; this will not be the case with *iron rust.* (2) The demonstration of the *corpuscles* by the aid of the *microscope;* (3) *spectroscopic* appearance of two dark absorption bands in the green rays, and at the junction of the green and yellow rays; (4) *chemical* tests, and as the action of guaiacum and ozonic ether, nitric acid, or caustic potash.

3. A *wound* (medicolegal) is an injury or lesion caused by mechanical or chemical means. *Incised wounds* are made by sharp-cutting instruments; the hemorrhage is free, the wound gaps, there is no bruising of the margins. *Punctured wounds* are deep wounds with a small orifice; they are made by narrow instruments. *Lacerated and contused wounds* are made by blunt instruments and by crushing; the soft parts are torn, the edges are bruised and ragged, the deep parts are infiltrated with blood; there is little free bleeding. *Gunshot wounds.*

A wound inflicted during life is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization. The shape and size of the wound do not always correspond with that of the instrument making it, because: (1) The edges of the wound may retract; (2) variation may occur on account of the tension or relaxation of the skin at the time the wound was inflicted; (3) the weapon may be withdrawn at a different angle from that at which it was introduced; (4) other factors are the size, weight, sharpness, or force applied to the weapon.

4. For the details of post-mortem examinations, see any textbook on Medical Jurisprudence (or Pathology). Lungs in which respiration has taken place float; those in which it has not taken place sink. Further, the lungs before respiration are situated at the back of the thorax and do not fill the cavity; whereas, after respiration, they fill the whole thorax. (*a*) *Artificial insufflation* is a difficult operation, and is not likely to be attempted by the mother, or anyone else. If done, the lungs would be bloodless, and there would be air in stomach and intestines. Practically, it need not be considered. (*b*) In cases of *putrefaction,* the air can be expelled by pressure, and none is found in the air cells; further, putrefaction of the lungs occurs late, and if found, and the lungs sink, the child was born dead. (*c*) If the flotation has been caused by *freezing,* the lungs would sink after being thawed out.

OBSTETRICS.

1. The *conjugate diameter* of the *inlet* of the pelvis is a line drawn down the middle of the sacral promontory to

the top of the symphysis pubis. It is about four inches in length. The *transverse diameter* of the *inlet* of the pelvis is a line drawn right across the pelvis from one lateral margin of the brim to the other. It is about five inches in length. The *conjugate diameter* of the *outlet* of the pelvis is a line drawn from the tip of the coccyx to the lower surface of the symphysis pubis. It is about five inches in length. The *transverse diameter* of the *outlet* of the pelvis is a line extending across the pelvis from one tuberosity of the ischium to the other. It is about four inches in length.

2. The cause of *rupture of the uterus* is: Strong uterine contraction in combination with some obstacle to the birth of the fetus. It is apt to occur in cases of contracted or deformed pelves, transverse presentation, obstruction from tumors, unduly large fetal head.

3. *Expectant plan:* Place the patient in bed, and if the bleeding is profuse, insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses (3½) of the fluid extract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of the gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary when the uterus refuses to contract and hemorrhage persists after the use of the curette." (Gould & Pyle's *Pocket Cyclopedia.*)

4. Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

5. *Causes of Transverse Presentation:* Prematurity of the labor; placenta prævia; narrowness of pelvic brim; great lateral obliquity of the uterus; multiple pregnancies; undue mobility of the child from excess of liquor amnii; accidental pressure externally from blows, falls, dress, etc.; repeated occurrence of cross-births in the same woman is probably due to a narrow pelvic brim. *Treatment:* Early correction of the presentation, converting it into a head, breech, or foot, by version (external, internal, or bipolar). In cases of arrested spontaneous evolution, with impaction, version is out of the question. The child is usually dead from compression; the method of delivery is embryotomy, usually decapitation.—(From King's *Obstetrics*).

6. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

7. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapse funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both. *Conditions necessary for the use of forceps* are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

8. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, and rectouterine. *During pregnancy* the uterus increases in *size* (from 3 to 12 inches in length; from 1½ to 9 inches in breadth), in weight (from about one ounce to two pounds, not including its contents). The cavity is enlarged over 500 times. All the tissues (muscles, ligaments, arteries, veins, lymphatics, and nerves become tremendously hypertrophied. The uterus also changes its position; at first it drops, later it gradually rises, till just before labor (when it again drops).

DISEASES OF CHILDREN.

1. Night cries; lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent); growing pains, sacroiliac disease, congenital dislocation of the hip, spinal caries and psoas abscess, infantile paralysis, lordosis, rickets, and rheumatism.

2. *Etiology:* Tuberculosis (traumatism and cold may be exciting causes). *Pathology:* It may begin in the synovial membrane, or acetabulum, or femur; if it begins in the bone it spreads to the synovial membrane and causes general infection of the joint. First of all the bacilli enter, multiply, and by their products cause irritation and new growth; as this advances embryonic connective tissue is formed, and the joint is filled with an effusion; later on caseation occurs, the joint is destroyed, and there may also be destruction of the surrounding tissues.

3. (1) *Stage of incubation:* Lasts about nine to twelve days, during which the child loses weight, but is not otherwise sick. (2) *Stage of invasion* lasts about four days, the child has catarrh, coryza, fever, sneezing, laryngitis; buccal spots appear about the first or second day, headache, anorexia, furred tongue, fever and diarrhea or vomiting may be present. The fever rises till the eruption appears; the pulse is rapid, 120 to 150. (3) *Stage of eruption:* Eruption generally appears on fourth day (for details see above, PRACTICE, No. 2); the fever and catarrh continue till the rash is fully developed. (4) *Stage of decline:* The eruption fades rapidly, is followed by desquamation, the other symptoms subside, but the bronchial catarrh is the last to disappear.

4. *Symptoms:* Sudden onset, severe localized pain, vomiting, tenesmus, and passage of bloody mucus. There is a sausage-like tumor in the abdomen; sometimes it can be felt in the rectum. Fecal impaction or appendicitis may simulate it, but in the former the swelling is less tender and is on the left side; in the latter there is fever, and the tumor is on the right side *Treatment:* Laparotomy and reduction of the bowel as soon as possible. Gentle manipulations, enemata, and opium have been suggested, but these should be adopted only when surgical relief is not available.

5. ATELECTASIS PULMONUM is collapse of the lung *Symptoms:* The child becomes livid or pale, also restless; he breathes quicker, and his temperature becomes subnormal; pinched features, cold sweats, and cessation of the cough are all noticed. There are bronchial breathing, absent or diminished vocal resonance, dullness on percussion at base and posterior border of lungs *Treatment:* The

child must be put at once in a hot mustard bath; then wrapped up in cotton wool, vomiting must be produced by an emetic; atropine sulphate (gr. 1/300-gr. 1/200) may be given hypodermically as a respiratory stimulant.

6. *To peptonize cow's milk:* Put into a bottle one pint of fresh cow's milk and 4 ounces of water; add a powder containing 5 grains of pancreatic extract and 15 grains of bicarbonate of sodium; shake the mixture. The mixture should be kept at a temperature of about 110° F., by placing the bottle in hot water; it should be occasionally shaken. For partial peptonization, this is continued for 6 to 20 minutes; for complete peptonization, two hours.

7. *The principal clinical changes that occur in the skeleton in rickets* are: Enlargement of the epiphyses of the long bones, curvatures are increased, flat bones have prominences or thickenings, green stick fractures are common, the head is large and square, the ribs are beaded, the fontanelles are open, dentition is delayed and irregular, the wrists and ankles are thickened.

8. Hydrocephalus, Syphilis, and Mollities ossium.

MATERIA MEDICA AND THERAPEUTICS.

(1) ℞ Tincturæ aconiti, ♏j.
Liquoris ammonii acetatis, ʒv.
Spiritus ætheris nitrosi, ʒj.
M. Signa: One tablespoonful every three hours in half a tumblerful of lemonade or effervescent water.

(2) ℞ Ammonii chloridi, gr. xxx.
Tincturæ opii camphoratæ.
Syrupi ipecacuanhæ, āā ♏iij.
Syrupi pruni virginianæ, ʒj.
Syrupi tolutani, q.s. ad ʒiv. Misce.
Signa: One teaspoonful every three hours.

℞ Morphinæ sulphatis, gr. j.
Ammonii chloridi, ʒj.
Spiritus chloroformi, ʒj.
Syrupi pruni virginianæ, ʒj.
Mist. glycyrrhizæ comp., ad ʒviij. Misce.
Signa: One tablespoonful every three hours.

2. CARBOLIC ACID. *Origin:* From coal tar oil, by fractional distillation; or it can be made synthetically. *Dose:* One grain. *Physiological action:* "Irritant; caustic; antiseptic; disinfectant; deodorant; parasiticidal; antizymotic; antipyretic; in solutions of moderate strength, locally anesthetic. The heart and respiration are at first stimulated and afterward depressed. Smokiness of the urine is a characteristic feature." *Treatment in case of poisoning:* Sodium sulphate or magnesium sulphate, warm mucilaginous drinks, cardiac and respiratory stimulants by hypodermic, warmth to the body, emetics, are all indicated.

3. The following is given by Einhorn: All substances that are liable to excite intensely the glands of the stomach must be excluded. Therefore all kinds of acids must be forbidden. The food should consist of material rich in albumin, while the quantity of starchy substances should be diminished. Thus all kinds of meat (even game), fish, oysters, eggs, milk should be taken in large quantities. Bread and butter are permitted. Potatoes, spinach, asparagus, green peas, farina, and rice should be taken only in small amounts. Whiskey and wines should, as a rule, be avoided. Cacao, weak tea, weak coffee, and beer can be given in moderate quantities.

4. APOMORPHINE HYDROCHLORIDE. *Dose:* As an emetic, gr. 1/10 subcutaneously; as an expectorant, gr. 1/30. *Physiological action:* It acts on the vomiting center in the medulla, hence is emetic; it increases pulse, blood pressure, and rate of respiration; it is also an expectorant. Its *indications* are chiefly those requiring a prompt emetic; also as an expectorant in bronchitis and lobular pneumonia.

5. SPIRITUS ÆTHERIS NITROSI is prepared from sodium nitrite, sulphuric acid, monosodic carbonate, potassium carbonate, alcohol, and water. *Dose:* 30 minims. *Therapeutic uses:* In feverishness, nausea, asthma, flatulence, as a mild diaphoretic, diuretic, carminative. *Common name:* Sweet spirit of nitre.

6. An agent which increases the action of the skin and promotes perspiration. (1) Alcohol, ʒss to ii; (2) Pulvis ipecacuaphæ et opii, gr. x to xx; (3) Spiritus ætheris nitrosi, ♏xxx; (4) Turkish bath.

7. *(a) Cardiac tonics* stimulate the cardiac muscle, and thus slow and strengthen its contractions. Examples: Digitalis and strophanthus. *(b) Cardiac stimulants* increase the force and frequency of the heart beat when the heart is depressed. Examples: Alcohol and ether.

8. *Cathartics* increase or hasten the intestinal evacuation. They act by: Increasing peristalsis, stimulating intestinal secretion, causing exosmosis of serum. Contraindicated in inflammation of stomach, intestines, or peritoneum, pregnancy, threatened intestinal hemorrhage.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of November 27, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	455	134
Diphtheria	392	29
Measles	263	7
Scarlet Fever	272	9
Smallpox	—	—
Varicella	138	—
Typhoid Fever	45	12
Whooping Cough	23	7
Cerebrospinal Meningitis	4	5
Malarial Fever	—	—
Totals	1,592	203

Diagnosis and Treatment of Puerperal Eclampsia.—Stern and Burnier sum up the characteristic symptoms of puerperal eclampsia and describe the differential diagnosis from neuroses and cerebral diseases. The cardinal symptoms are cephalalgia, high pulse tension, and albuminuria. They go on to describe the various forms of treatment. Blood letting is used by them as a routine procedure as soon as high tension occurs. Purgatives are of value. Veratrum viride has many advocates. The author does not look with favor on renal decortication, since the kidneys are not the only organs involved. Artificial serum injections are valuable as diuretics. The prognosis is bad in multiparæ, when there has been previous kidney disease, when the attack occurs some time before the normal time for labor, and when the attacks are repeated and prolonged.—*Gazette des Hôpitaux.*

Cardiac Complications in Articular Rheumatism in Children.—Marfan states that articular rheumatism may not be accompanied with much fever or much swelling of the joints in children, while at the same time there may occur an affection of the endocardium which is serious in nature. In babies there is prominence of the heart area and undulation of the chest, due to the softness of the chest wall. Compensation is more easily established in the child than in the adult, and cardiac hypertrophy rarely occurs. Mitral insufficiency is well tolerated. Pericardial adhesions are frequent and cause asystole, which results in hepatic stasis and increased liver dullness. Children who have had articular rheumatism are subject to attacks of fever without other cause, which indicate a chronic rheumatic condition.—*Journal de Médecine de Paris.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended November 26, 1909:

THE PRESENT STATUS OF THE TONSIL OPERATION. A COLLECTIVE INVESTIGATION.*

BY GEORGE L. RICHARDS, M.D.,

FALL RIVER, MASS.

OTOLOGIST AND LARYNGOLOGIST TO THE FALL RIVER UNION AND ST. ANNE'S HOSPITALS.

THIS paper is based on the replies to a series of questions addressed to prominent laryngologists in this country and Europe and on such of the recent literature as covers certain points concerning which information was requested. Replies to more or less of the questions were received from one hundred and thirty, and thirty-six articles in recent literature are also referred to.

The questions to be considered are the physiological function of the tonsil, its relation to tuberculosis and the cervical glands, its relation to rheumatism, the use of chemical caustics in its treatment, indications for removal, the choice of operation, the necessity for reoperation, present technique, the question of hemorrhage connected with the operation, and the result as to the voice.

The tonsil is a normal gland, the size of which varies within wide limits. All knowledge so far obtained seems to show that its function is normally one of defense against infection, the tendency to enlargement being a persistence of the process by which its function was evolved. In its normal state it offers comparatively little obstruction to the passage of food and air, but such condition is so variable that it is impossible to indicate exactly the minute structural changes separating the normal from the abnormal. It is pathogenic only when its presence is injurious to a degree more than overbalancing its value in whatever physiological acts of assimilation or defense it may have to perform. "The pits of the tonsils are retorts in which the germs are either destroyed or modified so that they may live at peace with their host, or they are allowed to pass through in such numbers as can be dealt with by internal processes without the destruction of the host. From various clinical facts, it seems likely it is the small, sunken, ragged tonsil, and not the large tonsil, which gives entrance to the dangerous germ" (Wright).

The experiments of Jonathan Wright show that dust and oil globules and also pathogenic organisms pass through the epithelium of the tonsil crypts, but the latter not as readily. The reason why one passes readily and the other only under certain conditions, is explained by the difference between the potentials of surface tension of the epithelial cell on one hand, and to the bacterium and dust particles on the other, due to the fact that the living matter is in a colloid state. The tonsil differs from the other lymph glands in that it has no afferent lymph vessels. The crypts are lined with an epithelium which does not form a compact unbroken barrier of protection, so that so far as any mechanical barrier is concerned, it presents an open door for microbic infection, the pockets and recesses being capable of retaining large numbers of bacteria. Hence it would seem that unless the vital resistance is considerably greater than in the surrounding structures, the tonsillar tissues ought to be the vulnerable spot in the throat. Experiments were made to determine whether, this being the case, certain anti-bodies would be found which would make this structure especially resistant to germ invasion. So far no considerable amount of immune bodies have been found, so that we are still uncertain as to the degree of vital resistance of the tonsillar structure. As the lymph chain of the neck presents a rather formidable barrier against the invasion of microorganisms, a large majority of patients suffering from microbic infection of the tonsils pass through the disease without any true bacteremia.

It has been stated that the tonsil is not a physiological organ, and various observations to this effect have been made. Bosworth says, "Incalculable mischief has resulted from the early anatomists describing the tonsil as a normal organ of the body." That it is such an organ, however, is undoubted, as the anatomical work of Mosher, based on the examination of embyros of four, five, six, and seven months, and full term infants, effectually disproves the statement that the tonsil is absent at birth. The reason that it is overlooked in the new-born child may be its position, since at birth the tonsillar opening and the tonsil are practically horizontal, and at such times the tonsil is more a part of the palate than of the wall of the pharynx. As the face grows downward, the tonsil also grows downward, forward, and inward.

As to the direct or apparently direct relation between enlarged cervical glands and the tonsil, one hundred and seventeen personal reports were positive; that is, that there is a direct relation between the two, the tonsil being apparently the gland through which the infecting agent comes, as evidenced by the cessation of the adenitis after removal of the tonsils.

The anatomical investigations of Poirier and George B. Wood have shown that the lymphatic drainage of the faucial tonsil runs directly to the upper deep cervical glands, which glands by a rich system of anastomosis are connected by efferents and afferents with practically all the lymph glands of the neck and head. The tonsillar lymph gland is generally situated just below the posterior belly

*Abstract of paper presented before the American Laryngological, Rhinological, and Otological Society at its fifteenth annual meeting, Atlantic City, June 3, 1909

of the diagastric where it crosses the anterior border of the sternomastoid. This spot is located just behind and below the angle of the jaw, and in tuberculous adenitis of the neck it is this gland which is almost invariably the first one to become enlarged, the others being involved subsequently. It would therefore seem as though this question had been sufficiently determined to admit of this relation being stated as a positive fact. That following the removal of the tonsil there may be in some instances an enlargement of the immediate glands, followed later by their subsidence, is an undoubted fact, and has been observed by me on several occasions. This is easily explained as a result of the traumatism from the operation, this giving rise to direct absorption of more or less septic material from the throat, and consequent gland enlargement. The contention of Chambers that infected cervical glands are always accompanied by large tonsils is hardly warranted. On the contrary, the investigations of Jonathan Wright and Lee M. Hurd have shown that in some cases of cervical adenitis the tonsil itself may be quite small and belong to the submerged type. There is no direct relationship between the size of the tonsil and the involvement of the cervical glands, nor is it always true that in all cases of enlarged cervical glands the tonsils are enlarged. Enlarged cervical glands are without doubt frequently the result of infection from or through diseased tonsils, but not all persons who have diseased tonsils have enlarged cervical glands; since the gland not infrequently has sufficient resisting power to ward off the infective process.

Fifty-seven of my correspondents had not observed any connection between the tonsil and tuberculosis; thirty-nine had; the others did not answer the question. Goodale has seen several such cases, already reported. Hurd reports seven cases out of nine in which the clinical diagnosis of tuberculous tonsillitis was made mainly from the condition of the cervical glands. In these cases Jonathan Wright found evidence of tubercle bacilli in the tonsils. He thinks the tuberculous cervical glands at the angle of the jaw are almost always secondary to primary tuberculosis of the tonsil.

Dr. Hurd and Dr. Wright have recently made investigations which show that the larger and freer the tonsil, the more it resists the invasion of harmful organisms; also that it is exceptional to find associated with such a tonsil much enlargement of the lymphatic glands. The small submerged tonsil is more likely to be the soil for the invasion of the tonsil with tuberculosis. Dr. Wright examined the tonsils in sixty cases where the protruding portion only was removed and did not find tuberculosis in any of them.

The tuberculous tonsil is usually pale, the crypts contain cheesy débris, the edge of the anterior pillar shows passive hyperemia, and the associated lymph glands are much enlarged. The stump of the partially removed tonsil is quite as liable to tuberculous infection as if originally submerged. Lermoyez regards chronic lesions of the tonsils as an open door to tuberculosis. Thompson advised removal of diseased tonsils in an adult woman, which was refused. She returned two years later for the removal of the tonsils and with a large mass of tuberculous glands in the neck. Recovery took place. There was no tuberculosis anywhere else in the body. Moure of Bordeaux does not believe that the tonsils are very often the starting point of tuberculosis.

The relation of the tonsil to rheumatism is one of the as-yet unsolved problems to which considerable attention is being given and concerning which I sought information. At the outset of such an inquiry one is confronted with the question as to what rheumatism is, and to this question there is as yet no unanimity of opinion. The older theories as to dependence on cold or wet and the uric acid theory seem about to be superseded by the theory of direct infection. Sufficient proof is perhaps not yet at hand to make this a certainty, but the tendency is all in this direction. All investigations so far made seem to show the probability of the accurateness of the infection theory. Frissell isolated an organism which, while culturally not readily distinguished from other diplococci or streptococci, yet had a special affinity for joints. This was shown by the fact that ten out of eleven rabbits injected had a polyarthritis, the other dying of pericarditis and pleurisy. Rheumatism may be due not to a specific coccus, but to a coccus group intimately allied, though perhaps indistinguishable from each other by present cultural methods, the individual strains of which would vary in virulence. He says: "Such a group might well contain the ordinary harmless streptococcus, a common habitant of the tonsil, so many of which were injected in our experiments into the animal circulation without producing symptoms; might include a variety causing an arthritis which tends to a spontaneous cure unless the number of the invading host be too great, and range up to the malignant streptococci, causing septic joints, septic endocarditis and pyemia." Exposure to cold and wet, so long held to be a potent factor in the causation of rheumatism, may be considered as lowering to the body resistance, thus giving the bacteria a chance to attack the temporarily unprotected organism.

Rosenheim, Ingals, Phillips, Welty, Levy, Ross, Cohen, Elliott and Robertson all cite instances of the positive relationship between rheumatism and tonsillar disease, and, in the main, the answers to my question as to whether rheumatism disappeared with the removal of the tonsil, showed that it either disappeared or that the attacks were less severe. I have recently removed some tonsils with diseased crypts in a woman of forty-two, who had rheumatism of the neck and shoulders many years. This entirely ceased after thorough enucleation of the tonsils and has not returned.

Aneurysm, appendicitis, erysipelas, meningitis, iritis, pleuritis, pericarditis, endocarditis, pneumonia, paraplegia, strabismus, nephritis, osteomyelitis, phlegmon, oöphoritis, orchitis, and general septic infection are all found in the literature as of tonsillar origin or occurring with or as a result of tonsillar inflammation. Investigation of all of these would lead me beyond my present field. They all show the possibility and probability of the tonsil as a portal of infection, and prove that whatever of protective value the tonsil may theoretically have, it is practically of little value; on the contrary, it is not infrequently a decided menace.

Of one hundred and twenty-five replies as to the use of chemical caustics, sixty-five did not use them in any form in the treatment of tonsillar troubles. By chemical caustics I mean those commonly used to reduce inflammatory growths, to lessen the size of the tonsil, to destroy diseased crypts, and, in general, any chemical agent which, applied directly, is used to bring the tonsil into a healthy condition. The chemical caustics which seem to be principally

used are: silver nitrate in varying strengths, and the fused salt on the probe, trichloracetic acid, chromic acid, carbolic acid with glycerine and silver nitrate, London and Vienna paste, sublimate in alcohol, lactic acid, and zinc chloride. Forty-two out of one hundred and twenty-five, or about 33 per cent., still use these to a greater or less extent, while eighteen formerly used them, but have now abandoned them.

While the advocates of these measures are decidedly in the minority, I cannot believe that the opinion of Dr. Freer, who regards chemical caustics as the resort of the timid manipulator who shuns surgery because he is afraid to attempt it, is a correct one, as many of the users of chemical caustics are good surgeons who cannot be said to fear the more radical measures. Certainly this cannot be said of Leland, Professor Chiari, Beck, D. C. Greene, Jr., Thomas Hubbard, Anderson, Roy, Clarke, Gleason, and others.

There occur in the practice of every laryngologist a certain number of diseased or hypertrophied tonsils in which, for one reason or another, radical surgery seems contraindicated, or, if indicated, is not accepted by the patient. In these cases I am satisfied from a considerable personal experience that the fused nitrate of silver on the probe, chromic acid, trichloracetic acid, melted and applied on a small tightly wound, right-angled cotton applicator, as well as many of the other agents mentioned, will, when carried deeply into the crypts, reduce the size of the tonsil very materially, and add to the comfort of the patient, and will be accepted many times when more radical measures will be refused. That these measures take the place of the complete removal of the tonsil when that is indicated, is not claimed, but that they have a place far more important than would be indicated by some of the opinions expressed cannot be doubted.

The indications for the removal of the tonsil are: recurring tonsillar abscess, or quinsy, recurrent simple tonsillitis, benign tumors, and new growths of any kind when their removal is not prejudicial to life, diseased crypts coexisting with tonsillitis and rheumatism, mouth breathing due to hypertrophy of the tonsils, middle ear inflammation apparently due to enlarged tonsils, impaired nutrition, systemic dyspnea, and general toxemia when of tonsillar origin.

General toxemia of tonsillar origin, impaired nutrition, and systemic dyspnea occur perhaps more often with the tonsils as a cause than is generally recognized. A recent case of my own illustrates this: A policeman in the habit of going to sleep and snoring whenever he sat down, very large and continually putting on flesh, was referred to me for examination of the throat. The faucial tonsils were so large that they met in the middle line. On their thorough enucleation the symptoms of dyspnea and general carbonic acid intoxication, as evidenced by the tendency to sleep, entirely disappeared, and the individual's entire character changed.

Remote reflexes such as vomiting, cough, chorea, irritable and granular pharynx, enlarged glands, when the tonsils are the probable cause, should have for treatment the removal of the tonsil.

With reference to tuberculosis, there seems to be a difference of opinion. If tuberculosis is evident or suspected, it may do to remove the tonsil when the case is seen very early, but so competent an observer as Frendenthal advises against removing the tonsils in advanced cases of tuberculosis, since he has found it not only of no advantage to the individual, but in many cases distinctly harmful.

With reference to children, if one accepts the dictum of Bosworth that the tonsil is not a normal gland at all, the hypertrophied tonsils in children should always be removed, even though there are no symptoms. It is probably the custom of most operators at the present time when operating for adenoids to remove the tonsils at the same time, even though there be no definite symptoms referable to these glands, on the ground that we are uncertain as to their function and know that they often are a source of trouble. Since apparently no one ever misses them when removed, it is claimed that it is better to give the child the advantage of the doubt and when the adenoid operation is done to remove the tonsils at the same time. On the other hand, if the tonsil has a distinct function of value to the individual it would seem that it ought not to be removed unless really causing trouble, and it is probable that this point of view will finally prevail, and fewer tonsils be removed at the time of the adenoid operation. G. H. Wright has recently shown that the enlargement of the tonsil at the time of the eruption of the various sets of molar teeth is a protective phenomenon, the tonsil diminishing in size after their full development. He thinks the tonsils ought not to be removed at these periods unless signs of positive disease are present.

In general, some of the statements seem to me too sweeping and some too conservative. For instance, Gildea and some others would remove every tonsil that shows any tendency to disease, whereas I think that many diseased tonsils are curative by local measures without removal. On the other hand, Gleitsman would remove only those tonsils that protrude beyond the palatine pillars. As many of the most troublesome tonsils, so far as the general economy is concerned, are those which do not protrude at all, this is too conservative. Welty of San Francisco says that all tonsils after twenty years are diseased and that when the tonsil is once diseased it predisposes the individual to any kind of infection, more especially the whole group of infectious diseases.

Several writers in speaking of the indications for the removal of the tonsils use the phrase "adherent pillars," "bad adhesions to the pillars," and the like. These terms seem to be misnomers, and I am quite of the opinion of Dr. Robert C. Myles, who has claimed for years in various papers written by him on the tonsils, that there is no such thing as adhesions to the pillars in a pathological sense. Anatomically, all tonsils are adherent to the pillars the tonsil being a gland with a capsule on its external side, set in between the anterior and posterior pillars, and necessarily attached to them on the anterior, posterior, and superior aspects, and to the mucous membrane adjoining the side of the root of the tongue on its inferior aspect. That the anterior pillar sometimes forms folds known respectively as the plica supratonsillaris and the plica infratonsillaris is well known, and this may explain the so-called adhesions of some writers. As a matter of fact, these plicæ are merely reduplications or folds of the free surface of the anterior pillar.

In cases in which this condition does not exist the mucous membrane of the edge of the pillar divides into two parts, one becoming continuous with the mucous membrane covering the tonsil, and the other continuous with the capsule of the tonsil, the two together forming the fast attachment of the

pillar to the tonsil, which is invariably present. This line of attachment is the first thing to be severed in the complete removal by whatever manner it may be done. This gives access to the edge of the capsule, which is attached to the superior constrictor of the pharynx and the adjacent areolar tissue. I cannot see, anatomically, any reason for speaking of "adherent tonsils" or "bad adhesions to the pillars" except as one refers to the complete removal of the tonsils, in which, owing to the character of the areolar tissue, it may be more difficult in some cases to perform complete dissection than in others. Also, the two folds going from the anterior pillar are sometimes thicker than at others, but they are true anatomical structures and always present.

As to the choice between tonsillotomy or tonsillectomy; twenty-eight favored tonsillotomy; fifty-seven favored tonsillectomy; thirty-two, tonsillotomy in young children for simple hypertrophy, tonsillectomy in older children or in the presence of distinct pathological changes at any age; two, tonsillotomy in adults, tonsillectomy in children. The opinions given in answer to the question as to the reporter's preference for tonsillotomy or tonsillectomy show a gradual change towards the more thorough operation of tonsillectomy; since only twenty-eight out of the entire number still range themselves as absolutely on the side of tonsillotomy, although the answers in the way of technique would seem to show that some of the operators are content with rather less than the absolute removal of the tonsil gland. The tendency, however, is in that direction, and it is probably only a matter of a few years when the others—the thirty-two who use tonsillotomy for young children for simple hypertrophy and tonsillectomy in older children or when the tonsil is manifestly diseased, will use tonsillectomy in all their cases; since it is certainly not rational to remove a gland at all unless one removes it as thoroughly as possible and with a view to the prevention of any possible future complication.

To take some answers a little more in detail: Gleason of Philadelphia advocates tonsillotomy in simple hypertrophy, because it requires no general anesthesia and there is no risk. In recurrent tonsillitis or quinsy, with retention of cheesy matter, he advocates tonsillectomy, but with reluctance and with a feeling that the remedy may be worse than the disease, saying that it is theoretically comparable with the rough surgery of the Civil War. To this I would reply that a clean tonsillectomy is not at all rough surgery, but quite the proper operation for the purpose for which it is done. Dr. Farlow uses tonsillotomy generally, because it has less risk, and thinks that tonsillectomy has a risk out of proportion to its advantages. Dr. Frank Miller says that tonsillotomy correctly done never causes hemorrhage, but there is bleeding if all the tonsil comes out, leaving the capsule. Tonsillectomy is often dangerous, with a constant hemorrhage five to eight hours after, when not expected. Prof. Chiari practices tonsillotomy only, as the remaining portion of the gland atrophies and in tonsillectomy there is danger of injury to the tonsillar artery in the capsule. Personal observation in Prof. Chiari's clinic corroborates this statement as to practice. I have never seen any operation done there except tonsillotomy. Ross, Gerber, Pooley, and Sir Felix Semon have found tonsillotomy sufficient with very few exceptions. As showing that the leaven of completeness in tonsillar surgery has not leavened the whole lump, such experienced observers as E. L. Shurley and Dr. Gleitsman prefer tonsillotomy and see no reason why the whole organ must be removed. Ballenger performs tonsillectomy, removing the tonsil with the capsule intact. The crypts of the tonsil extend to the capsule, and it is the crypts that usually form the atrium of infection. If the capsule is not removed, the surgeon is not sure all the diseased tissue is removed. If tonsillotomy is practised, a careless and imperfect operation is too often passed as a sufficient operation. A partial operation is frequently followed by recurrent tonsillitis and by the regrowth of the tonsil tissue. He has never seen recurrence after removing the tonsil with the capsule intact. Contrary to the oft-expressed opinion as regards the difference in procedure between children and adults, Theisen of Albany always uses tonsillectomy in childhood, since incomplete removal is frequently followed by recurrences of lymphatic tissue. In adults he finds tonsillotomy often sufficient. If one is to differentiate at all between the two, the author regards this opinion as more nearly correct than that of tonsillotomy in children and tonsillectomy in adults.

In reply to the question as to the necessity of repeating operations for the removal of the tonsil, one hundred and six reported in the affirmative, that is, they had operated on the same individual more than once, in some cases after a previous operation by some other surgeon; ten replied in the negative, and five said that they had reoperated after others, but not after themselves. This statement is easily explainable, as it not infrequently happens that a second operation is done by another operator Nearly every operator who now does tonsillectomy reported that all of his secondary operations had been done after tonsillotomy and that no occasion had been found to reoperate after tonsillectomies. That the tonsillar tissue seems in a measure to reform when the basal portion is left is evidenced by the testimony of several good observers, such as Emil Mayer, Gleitsmann, Berens, Hajek, Gradle, Loganturner, and others. Not to quote individuals further, the practical unanimity of opinion as to the occasional need for reoperation would seem to show that tonsillotomy is an incomplete operation and that it does not fulfill, as so many of its advocates aver, all the desired results. Certainly the writer has had this experience, *i. e.* the necessity of secondary operations in certain cases in which he has performed tonsillotomy. On the other hand, he has seen many satisfactory results after tonsillotomy.

There is quite a difference in usage in regard to the question of anesthesia. In operations on children several operators use no anesthetic whatever, and it is well known that it is not the custom on the continent of Europe to anesthetize children for adenoid and tonsil operations. In America, most parents prefer that the child be spared the shock and pain of the operation, even though it be not so very great. Anesthesia has also the advantage that it allows time enough to do a better operation, especially in the dissection of the tonsil, and with a few exceptions all of the surgeons reporting to me are in the habit of using anesthesia in operations on children. For local anesthesia, cocaine in some form or other is mostly in vogue, either by injection or painted on in varying strengths. The reports on this question were as follows: Sixty-three use ether as the anesthetic for children; ten gas and ether; ten, chloroform; one uses chloro-

form up to twelve years of age, ether after this age; seven, ethyl-chloride; five, somnoform; two, nitrous oxide; three, ethyl-bromide; two, ethyl-chlorid and chloroform. Operation under general anesthesia should be done in the hospital or at home, and not in one's office.

As regards children operated on under general anesthesia, the dorsal position is preferred by twenty-five, the prone on one side or the other by forty, the semi-recumbent by two, the Rose or Trendelenburg by seven, and the upright by twenty-seven. It is somewhat remarkable that the upright position is used almost exclusively by operators in the New England States and by several scattered over the West and South who were former house pupils in Boston hospitals.

Phillips believes the upright position to be unnecessary from the standpoint of skill, and to be fraught with danger of syncope, suffocation, and flooding of the larynx, and of pneumonia. Packard thinks this position adds greatly to the danger of ether and chloroform and to the risk of detached tissue entering the larynx and causing dangerous obstruction.

On comparing the reports of accidents, hemorrhage, and the like, I do not find that they have been any more common in those who operated in the upright position than in those who operated in the dorsal or recumbent. The operating-room nurse in our own hospital has told me that all the unpleasant experiences coming under her observation in the past four years were in cases operated upon in the prone position. Without exception, everyone who operates on adults under local anesthesia does so in the upright position, and as all those who use no anesthetic whatever use the upright position, it would seem from anatomic reasons of position and comfort of vision that the upright position was preferable to the recumbent or dorsal, unless there are manifest reasons why one is much safer than the other. I almost invariably operate in the upright position, in adults as well as children. I usually give general anesthesia, and when completely anesthetized, the patient is put in a chair facing the light, or else I use a head mirror and artificial light. The patient is not so profoundly anesthetized as to abolish the reflexes, and I have not had, so far as I know, any accident due to position. It is true that in a demonstration at a meeting of this society I had an unfortunate experience in an operation done in the upright position, tracheotomy having been required, as is known to some of you. That, however, as I said to you at the time, was due entirely to a fault in the matter of technique in the introduction of the gauze sponge too heavily soaked in peroxide of hydrogen, with resultant inhalation of gas, and was not at all dependent on the position which was used. The same thing was just as likely to have occurred had the child been in a recumbent position. Recovery took place and no accident occurred in the three other cases done at the same time and in the same position, nor have I in the year that has elapsed had any trouble incident to the question of position. I therefore defend the upright position as perfectly proper and to be used by those operators who prefer it, without in the least condemning the prone or horizontal position, since so far as thoroughness is concerned it is possible to do the operation as thoroughly in one position as in the other. In the case of severe hemorrhage, where there was danger of swallowing considerable blood and where a large pad of pressure material had to be introduced, the Trendelenburg or Rose position would probably be more advantageous as interfering less with respiration. I occasionally operate on adults in some one of the recumbent positions. The advantage of the upright position is that the anatomic relationships are normal and one has a good view of the entire area. In my operations the amount of blood vomited afterwards is comparatively slight and I have found no discomfort in any way from it.

The technique of tonsillotomy seems to have undergone few changes in recent years, with the exception that the punch is used by many in the attempt to remove what may be left after tonsillotomy. The grasping forceps are also more used in order to get more of the tonsil into the ring, and pressure on the outside is used by many. The technique as given by the operator citing the largest number of tonsillotomies is extremely simple, his technique for children and adults being given as follows: "Patient seated in a chair—cocaine—Mathieu's tonsillotome—cut."

As to the results in tonsillotomy, it cannot be denied that a good tonsillotomy followed by the punch removes the greater portion of the offending gland. I have taken occasion to examine a good many of my earlier cases of tonsillotomy, some of them after the lapse of many years, and have found, in the main, that the results have been satisfactory. In several of them, however, there has been quite too much of the gland remaining to satisfy me that the operation had done all that it might have done for the individual had the tonsil been completely enucleated, and there have been a few peritonsillar abscesses.

The replies to the question as to the technique of tonsillectomy show that each operator starts out to remove the gland, but evidently with varying conceptions as to how this is best accomplished. There was a difference of opinion as to the capsule, some saying that they leave the capsule, or punch out everything but the capsule. Thorough enucleation of the gland, however, requires the removal of the tonsil with the capsule, and this is evidenced by the reports of the technique of all those who really do a thorough enucleation. To enucleate requires first the separation of the attachment of the outer and inner surface of the tonsil to the mucous membrane and edge of the anterior pillar, which edge at this point divides into two layers, one continuous with the capsule and the other continuous with the mucous membrane of the tonsil surface, the free mucous portion of this, with probably a few muscle fibers, sometimes folding over the front of the tonsil and sometimes above and below, forming the so-called plicæ. The tonsil is attached to the posterior pillar as well, and to the superior border where the two pillars meet. Once this separation is made, the tonsil is then detached with its capsule from its attachment by fibrous fascia to the inner border of the superior constrictor muscle, some of the fibers of which seem to run into the capsule at times, so that sometimes this detachment is impossible without the removal of an occasional muscular fiber. In other cases the capsule can be separated cleanly from the muscle without removing a single muscular fiber. To accomplish this requires some form of dissecting instrument, sharp or blunt. These are various, consisting of knives, scissors, and blunt spuds, which are used while traction is being made on the tonsil. Many operators, myself included, find that this separation is made very readily by the

finger, which brings into play the sense of touch, and with a sharp clean finger nail it is in most instances easy to make the first line of cleavage with the nail and then to follow it up until the tonsil is pretty thoroughly shelled out, when any detaching instrument can be thrown over the portion that remains, which is the portion at the base of the tongue. This line of cleavage may be thinnest and easiest found anteriorly or posteriorly. By carrying the finger along the line of attachment, both anteriorly and posteriorly, it will usually be found easily, and when found it is possible to get behind the capsule. At times it is difficult to separate the tonsil edge from the pillar, either front or back, but it can be done. When this is the case, some one of the several forms of right-angled or pointed separators is of advantage. I have used with satisfaction Freer's right-angled knife and Yankauer's tonsil separator, but with tip sharpened. As soon as the line of cleavage is found, the rest of the dissection is made with the finger. The upper third of the posterior pillar and the upper half of the anterior pillar are the points where separation is most easily attained. One is often surprised to find when using this method how high up into the palatal fold the tonsil or so-called velar lobe extends. When the operation is finished, one side of the palatine arch may appear much higher than the other. This condition soon adjusts itself and is not evident a few weeks later.

Other surgeons, grasping the tonsil, take knife or scissors, cut along the edge of the pillar until the white edge of the capsule is reached, and then follow the dissection with a knife, scissors, or blunt instrument. Quite a variety of instrumental methods can be used to accomplish exactly the same result; namely, the shelling out of the tonsil from its bed and the cutting off of its attachment at its lower border near the base of the tongue. One can do this with the finger entirely without the use of any instruments other than the traction forceps, as is proven by Dr. Charles W. Richardson and others. I was under the impression that I was one of the first to use the finger nail as a dissector out of the tonsil, and was certainly one of the first in American literature to describe a finger-nail dissection. However, I am by no means the earliest in the description of this, as it was very thoroughly described by Lambert Lack in the *Journal of Laryngology* in 1901.

One of the advantages in using the finger-nail is that in buried tonsils where it is sometimes hard to obtain a good traction with the forceps without tearing, and where there may be danger of cutting the pillar with sharp instruments, it is possible by the sense of touch alone to do nearly the entire dissection. It is my own habit not to apply any form of traction forceps until after the dissection is partially made and the tonsil pedunculated. The forceps are then less likely to tear through, whatever their type. In my first operations of this kind, I seized the tonsil with the grasping forceps, having the tonsillotome swinging on the blades. Afterwards, like several others, I devised one of the many types of ringless tonsil forceps, with the idea that after once getting hold it would be possible to throw the detaching instrument over the forceps and the tonsil.

As to the type of cutting instrument, these vary with individual usage. Personally, I prefer a ring tonsillotome of the old Mathieu type with the forks cut off. (I think it is known in the instrument catalogues as Casselberry's.) Before getting these, I had removed all the forks from my old instruments, and they work equally well. The snare answers very well, is efficient, and is preferred by some; it follows the surface of the capsule more closely and is less likely to remove any muscular fibers. I do not feel certain whether there is less hemorrhage after its use. Bosworth and many others think there is. A thorough operation can be done with the Robertson scissors, and Robertson, who demonstrated this method at the meeting of the American Medical Association at New Orleans, is entitled to very much of the credit for the operation of thorough enucleation, and was one of the first to describe the method called after him. His operation consisted of detachment from the pillars with a double-edge sickle knife, the grasping of the tonsil with a vulsellum, and then going in behind with specially constructed scissors. He made the statement, which has been borne out by my own experience in some instances at least, that if bleeding occurred afterward, some portion of the tonsil had been left. This, however, is not always the case, as the pillar may be injured. I have sometimes found that in the final cutting or in the necessary dissection a piece of tonsil may be left above or even below, and after detachment of the tonsil I invariably feel with the finger between the pillars and above where they meet, to see if any portion of the tonsil can possibly be left; if so, it is again grasped with the forceps. Care should be taken not to have too much traction when the final detachment is made, on account of the danger of making too deep a wound at the base of the tonsil and also on account of the danger of possible hemorrhage.

Yankauer, Goodale, Worthington, West, Freer, and others all do a thorough enucleation by various methods, not differing very essentially from one another in principle, all having for their object the removal of the tonsil with its capsule, with the minimum amount of traumatism and danger. It cannot be denied that the throat is sorer after tonsillectomy than after the old tonsillotomy, but the result justifies the discomfort. In the adult a week elapses before the soreness disappears.

It would seem from the reports given that adult tonsils are removed less thoroughly, many contenting themselves with punching out the adult tonsil or with less thorough dissection. If, however, the adult tonsil is to be removed for rheumatism, it would seem necessary to do it as thoroughly as possible, which would require complete dissection and either general anesthesia or very thorough local anesthesia. The whole trend of thought on the subject of technique seems to be in favor of complete enucleation with the capsule, and the accidents so far seem to be few.

In reply to the question, "How often and in what class of cases have you had hemorrhage?" I received a variety of interesting answers, showing great difference in individual experience. Adding them up and getting the totals, there were one hundred and seventy-nine cases of primary hemorrhage, and fifty-four of secondary hemorrhage. Individually they vary from none at all, reported by several, to as high as ten per cent. bleeding sharply at the time. It would seem as though there must be a great variation in what is understood as primary hemorrhage. As to the secondary, there can be but little difference of opinion. These have occurred all the way from one to seven days after the oper-

ation, several of them to the point of alarm and not all of them in bleeders by any means. Two of my own cases had secondary hemorrhages days afterwards, one somewhat alarming (six days after), and another one five days after. As to primary hemorrhage, we are wont to think if they are at all serious that we have to do with a bleeder, and of course this is sometimes the case. The fact remains, however, that a tonsil operation is sometimes followed by bleeding, and that possibility should always be considered. I have for this reason ceased to do the tonsil operation in my office and have the patient go home, nor do I consider it wise to operate on females during the menses. On one occasion I did an office operation for tonsillotomy on an adult under local anesthesia with cocaine and adrenalin. There was no bleeding at the time of operation, but four hours afterwards there was a most alarming hemorrhage which was controlled with difficulty. Since that time I have abandoned the use of any adrenalin preparation in the removal of tonsils by local anesthesia, preferring to have my bleeding at the time of operation rather than several hours later. I have several times seen troublesome bleeding after tonsil operations both with local and general anesthesia.

Comparing tonsillotomy with tonsillectomy, I have found, contrary to some observers, that there is less bleeding after tonsillectomy than after tonsillotomy. Nevertheless, I have seen one case in a child with most severe bleeding a few hours after tonsillectomy, and have twice tied bleeding vessels in adults. As my experience covers only a small number of cases compared with that of many operators—perhaps a thousand in all—and as some of my reports come from men of far larger experience, I am somewhat surprised at their freedom from unpleasant hemorrhage. For instance, Griffin reports that he has done over thirty thousand cases of tonsillotomy and has had only one hemorrhage, and that one in a bleeder. These were all done with the Mathieu tonsillotome. The points from which the bleeding comes seem to be the base of the tonsil and the region of the pillars, seldom being due to the injury of a really large artery. I regret that I cannot go over the details of these reports, as it would consume too much space, but some of them I may refer to: Holmes, Packard, Miller, Stout, Bryant, Barnhill, Kenefick, Beck, Cohen, Getchell, Chiari, Thrasher, Luc, Sir Felix Semon, Hajek, and many others, all reported cases of serious hemorrhage.

Ballenger says that he does not find that hemorrhage depends to any extent upon the class of cases, but upon whether the muscles forming the sinus tonsillaris are injured. In all classes of cases hemorrhage may follow the decapitation of the tonsil, perhaps more often in fibrous or sclerotic tonsils. Otherwise the hemorrhage largely depends upon the injury of the muscles of the anterior and posterior pillars and the superior constrictor of the pharynx. As the arteries are either buried in or are external to these muscles, they will not be injured if the muscles are not injured. The tonsillar artery, while external to the superior constrictor muscle of the pharynx, is one large stem. In passing through, it subdivides into three or four branches. If, therefore, this muscle is injured, the main stream may be divided and the hemorrhage be great, whereas if the tonsil is removed without injury to this muscle, only the branches are divided and the hemorrhage is correspondingly less.

Welty thinks all hemorrhage after tonsil operations is dependent upon the amount of tonsillar tissue remaining. Pynchon gives his clients a most elaborate paper with minute directions as to what to do in case of hemorrhage, so that he must consider this occurs sufficiently often to render this necessary. There are four pages of closely printed directions and two pictures in this circular. He gives chloride of calcium by the mouth or rectum in 10-grain doses in two ounces of water repeated hourly for three doses. After three days it is discontinued for a few hours before again being used. Forty to sixty grains in 24 hours is the maximum dose. He also mentions lactate of calcium in single doses of 30 grains.

I have also collated many cases of hemorrhage from the recent literature, but I refer now only to Heuking, who reports six cases of severe hemorrhage occurring in his practice, in all of which the operation was done with the tonsillotome, and the injury was at the junction of the anterior and posterior pillars or else at the beginning of the posterior pillar. In none was the hemorrhage from the stump of the injured tonsil. They were all stopped by digital compression with gauze sponge, and might have been stopped with compression forceps. They were all done without traction. The ages varied from fifteen to sixty years. Death nearly occurred in several of the cases. The free border of the posterior pillar was caught in the ring with the tonsillotome, thus leaving an open vessel without good opportunity for retraction, and not particularly visible. Owing to the action of the msucle, coagulation was hindered by coughing, vomiting, and gagging.

Without carrying these statistics further, we can see that with rare exceptions every operator doing any amount of work has had hemorrhage at one time or another. It seems to the writer that this is less likely to occur after the operation of tonsillectomy, but he does not deny that it may and does occur after this operation. It seems most likely to come from the vessels around the base of the tonsils or from injury to the pillars, since the vessels of the muscular tissue of the superior constrictor, when no portion of the tonsil is left, usually retract to such an extent as completely to close the mouths of the vessels. As to the best method of handling hemorrhage, simple pressure with the tonsil hemostat, the tying of the vessel with a ligature, soaking the cotton or gauze pledget which is used for pressure in weak solution of nitrate of silver, wringing out the excess, and the use of peroxide of hydrogen, all have their place. In using peroxide of hydrogen, one must be careful that there is no free fluid or no excess on the sponge, since if there is, too great formation of gas may occur and some of the gas be inhaled into the trachea, with resultant difficulty in breathing. Suturing the pillars over a pad of gauze and the use of lactate of calcium may be required. Dr. Chevalier Jackson, of Pittsburgh, has reported six cases of ligature of the external carotid for hemorrhage. This would seem to be required but seldom, since in most instances it is possible to handle cases even of severe hemorrhage without proceeding to so formidable an operation. From the reported cases there is no particular proof that dangerous bleeding occurs more often in adults than in children. There seems to be sufficient testimony in favor of the use of calcium chloride and calcium lactate as a preventive of hemorrhage to warrant their further use. Pierce gives

the chloride a week before operation; most operators for three days.

I have investigated somewhat the statement made that the tonsil operation injures the voice, and find that by far the great majority of operators have seen only improvement and not injury to the voice. Those physicians, however, having most to do with professional singers have given somewhat guarded replies and admit that for the time at least there is an alteration in the voice, followed later, as a rule, by improvement. Shurley, Gleason, and Lambert Lack have reported injury to the singing voice. Others have found impairment for a few weeks, but the ultimate effect was good. I believe that the range and power of the voice should be increased after complete tonsillectomy, provided the pillars are uninjured, as in many cases, the tonsil, by its firm attachment to the pillars, especially if it is enlarged, hinders the mobility of the muscles. I have always believed that the reported cases of injury to the voice were due to the fact that the tonsil stumps were still present, hindering the mobility of the muscular action, or else that the pillars themselves were injured by the operation.

Of accidents other than hemorrhage, injuries to the uvula, the pillars, and the palate, mild cellulitis, severe surgical shock, simple infection, deep cervical cellulitis, respiratory arrest requiring tracheotomy, torticollis, and alteration of speech from injury to the pillars are all reported.

Of deaths: a case of general staphylococcus infection, one from pneumonia, one from chloroform anesthesia, one from adrenalin poisoning, one from spasm of the glottis, one from sepsis or from malignant scarlet fever, and one case from throat abscess are given.

CONCLUSIONS.

Further study of the physiology of the tonsil seems desirable, as it is still somewhat of a question as to how much importance the tonsil may be at certain periods of life, and if of value in the economy, it ought not to be removed to as great an extent as at present.

Under diseased conditions, the tonsil is one of the avenues of entrance for the tubercle bacillus and for the specific organism of rheumatism, whatever that may be. There is a sufficient amount of undoubted clinical evidence to show that it is also the avenue from which the infection enters for many other constitutional diseases.

The small submerged tonsil is quite as apt to be deleterious to the economy as the large one.

Local measures in the treatment of tonsillar troubles have their place.

The indications for removal are any condition in which it is evident that the tonsil is exerting an injurious influence upon the entire organism which cannot be averted by local treatment.

Ether is the safest general anesthetic.

According to the testimony of most observers, some form of horizontal position is the safest for general anesthesia, though the writer believes that the upright position, properly safeguarded, is equally safe.

Tonsillectomy should always be done in preference to tonsillotomy. Any method that removes the tonsil *in toto*, with its capsule, with the least traumatism, is satisfactory.

The voice is improved rather than injured, provided the pillars of the fauces are uninjured in the operation.

SOME NOTES ON THE LAST EPIDEMIC OF YELLOW FEVER IN CUBA.

By POWELL C. FAUNTLEROY,

MAJOR, MEDICAL CORPS, U. S. ARMY.

In the first week of June, 1908, a case of yellow fever was found in Santiago de Cuba. The victim was a Spaniard who had been lately working at the iron mines near Daiquirí, a small village on the south coast of Cuba, about fifteen miles from Santiago de Cuba. As usual in the case of Spainards of this class a connected account of his daily whereabouts could not be obtained. Suspicion was directed towards these mines and an inspection of the different groups of which they consisted was made and a careful inquiry made at their hospital into the history of all the patients admitted for the previous few months. This disclosed the fact that at least twelve cases had been admitted under the diagnosis of malaria and nephritis from June 26 to July 15, and three had died. The physician of these mines did not know how to use a microscope and made his diagnosis in the good old way without bothering about such a troublesome instrument. His rule, however, was to examine the urine of all patients; but, as he said, the hard work and coarse salt food of these miners sooner or later caused albuminuria and therefore that was not to be taken too seriously.

The port of Daiquirí was quarantined, a sanitary force was immediately sent, and the work of eradicating the disease in this locality was inaugurated. For various reasons the progress of this work was not satisfactory and I was sent from Havana by Major J. R. Kean, M.C., U. S. A., adviser to the Sanitary Department of Cuba, to take charge of the situation. I left Havana on the night of July 14, and arrived at the mines and took charge of the work July 18. Two more cases had been admitted to the hospital, making fifteen in all that were known to have occurred to that date. On looking over the situation I found that about 36 square miles of territory were infected and the foci so difficult to approach and the distance so great that a large force was necessary to prevent further spread of the disease. Although none of these mines is more than 3½ miles from the seashore, some are 1200 ft. above sea-level. By examination of the accompanying picture, which illustrates the character of the locality as a whole, it will be seen that it was made up of very high and very steep mountain spurs with intervening cañon like valleys. There were two settlements, Daiquirí proper on the seashore, and the mining town of Vinent, 3 miles to the northeast, in the mountains. Besides these there were eight different groups of mines each with their large barracks, stores, etc. A railroad connected the various groups, the ore being sent down on long incline chutes to the railroad below which finally carried it to the port of Daiquirí, where it was loaded on vessels and from there taken to the company's smelter in the United States.

Besides these two villages and widely separated groups of barracks, there were a number of thatched huts, known as bohios, to be found near the barracks and also down in the deep valleys. These bohios were occupied by retired miners, who raised cattle and did a little farming. They were difficult to find and very hard to approach. They were found later to play a most important part in maintaining the epidemic, the miners resorting to them for care whenever they were sick rather than go to the hospital, as they did not like to be put on a milk

diet, and, moreover, their pay was stopped as long as the doctor saw fit to keep them there. Their custom, on getting sick, was to go down into the valley and live on mangoes. If they got well in two or three days, they returned to work and no one was the wiser. Only when they thought they were not going to get better would they go to the hospital. The mosquitos in these bohios became infected and so a man with some other trouble, coming to them, would contract yellow fever and finally arrive at the hospital, but could not be induced to tell where he had been. This class of Spaniards is very secretive, suspicious, and prone to lie even when the truth would serve them better. There were about 3000 people in this territory, and the most of them were non-immune Spainards.

The maritime and land quarantines were established. A large force of rural guards was placed at my disposal. Posts were established at every pass and outlet, and all roads and trails were patrolled night and day. Nonimmunes were not allowed to enter this territory, and none to go out except on important business, and then only on putting up $25, which was forfeited if they did not report to the Sanitary Officer of the town to which they were going immediately on arrival and thereafter daily for five days. A pass, giving name, personal description, date, and place of leaving and destination, countersigned by myself and stamped with the government seal, was the only authority that the guards were permitted to recognize. Persons breaking this quarantine were severely dealt with by the local magistrates. In a few days the locality was effectually quarantined, the company's hospital was made mosquito proof, and a special ward was set aside for suspects. The sanitary force was increased to about 300 and ponies enough were hired to mount all inspectors and census takers and as many carts as could be used were obtained. The necessary steps were taken to feed and shelter this force.

The territory was subdivided and an adequate number of men were put in each subdivision to enumerate the inhabitants quickly, take their temperatures daily, and map the locality, giving location of all dwellings, roads, and trails. All sick were immediately sent to the hospital under guard. The daily reports of these men were carefully watched and people missed out of their districts were looked for until found. Inspectors were sent everywhere to instruct the people in regard to the danger of water deposits, and what was expected of them in maintaining a sanitary condition of the premises. Large organized gangs with the necessary tools were put in each subdivision to clean it up, drain, fill up or cover with wire gauze all water deposits. All tin cans, bottles, and other rubbish were buried, and weeds were cut down and burned. No unnecessary water deposits were permitted and all those authorized were definitely recorded and noted on the maps. All barracks and dwellings were screened. Large petrolizing squads, under trained inspectors, were put in each subdivision with instructions to petrolize every ditch, drain, or uncovered water deposit daily, destroy all unauthorized ones and report all cases of infraction of sanitary rules. It was not many days before larvæ could not be found anywhere.

A large fumigation gang was organized and every dwelling place, hospital, stable, shop, store, office, and house of every description in each district was systematically and thoroughly fumigated with sulphur, using 5 lbs. per 1000 cu. ft. The doors and windows were first quietly closed, the entire house, including porch and basement, covered with large pieces of heavy canvas, using paper and paste to seal all holes and places where the canvas overlapped.

Fig. 1.—Showing the manner of covering houses with canvas.

A small opening was left through which the sulphur and frying pans, in which it was to be burned, were carried and distributed inside the house, and under it when practicable. Some of these pieces of canvas were very large, requiring, when folded up in long rolls, as many as fifteen men to carry one.

All these squads were carefully organized with a foreman to every ten men, so that they become very expert in covering a house. As many houses in a group as possible were covered simultaneously so that no house was left into which the mosquitos could fly and hide and so escape fumigation. (See accompanying picture of an entire settlement covered with canvas.) Whenever a suspected case of yellow fever was found in a dwelling it was refumigated and a man kept in it all night to report if any mosquitos were about. It was refumigated until none could be found. This was very hard work because of the mountainous country over which all materials had to be carried. The various divisions of the work were under trained men, and their work was carefully inspected and supervised.

largely due. Not another case of yellow fever has occurred to date in that locality. The work was expensive, but not more so than thoroughness demanded, and when the great loss to the country incident to a yellow fever epidemic is considered, the cost was very small. The origin of this epidemic could not be positively ascertained, but suspicion strongly pointed to Port Said at the mouth of the Orinoco River.

Incidentally to this anti-yellow fever work, the culex and anopheles mosquitos almost entirely disappeared along with the stegomyia. The only mosquitos to be found at the end of this work were the small spider mosquitos that bred in the land crab holes along the water courses and the seashore, and the small culex mosquito that was found to breed in the rainwater that collects in the cup-like cavity between the leaves of the Curujey. The Curujey is a parasitical plant (in appearance like the top of a pineapple), that is to be seen everywhere in Cuba and in some forests covering the limbs of almost every tree. The Cuban insurgents during their

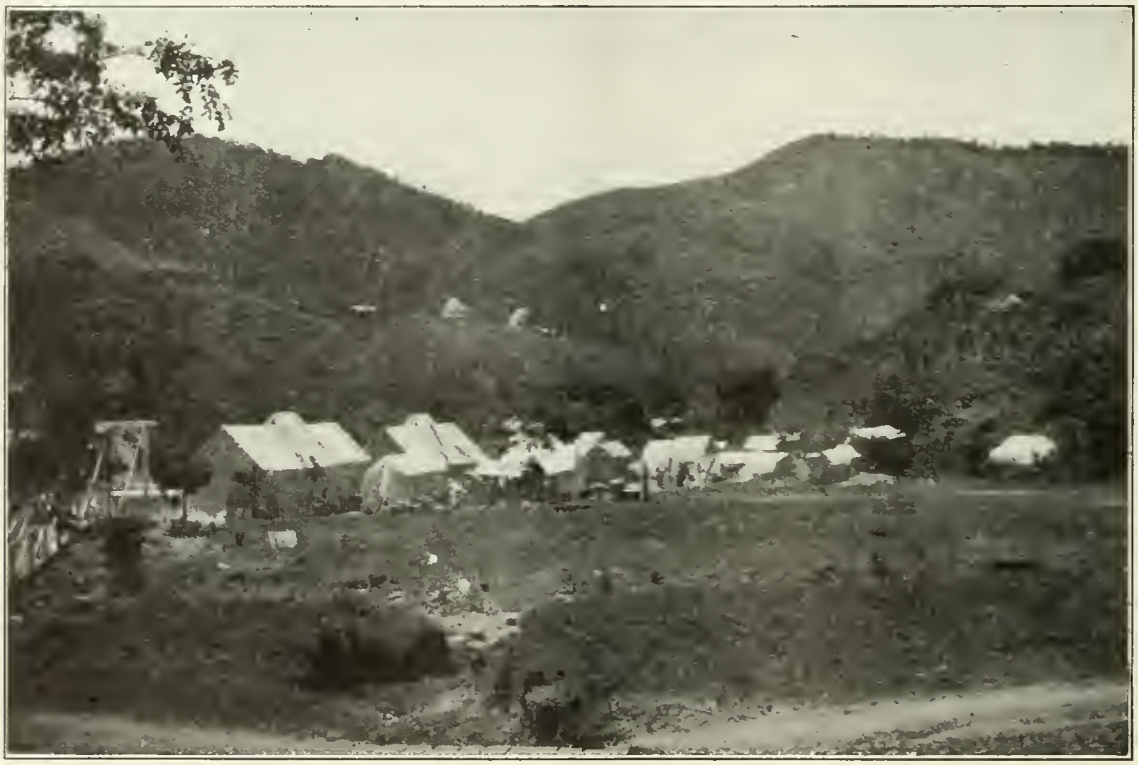

Fig. 2.—Showing twenty-two houses being covered simultaneou sly with canvas preparatory to fumigating them with sulphur.

A laboratory was established in the beginning and specimens of blood, urine, etc., were systematically examined. Eight more cases of yellow fever occurred, the last one on July 31, 1908, making in all twenty-three cases, six of which ended fatally.

The men who did this sanitary work were Cubans from Santiago de Cuba and, on the whole, I have nothing but praise for the way in which they stuck to their duty under the most trying conditions of heat and rain, and overcame the great obstacles encountered in this rough country. There were, however, several strikes which required considerable diplomacy to settle, and a considerable fight between the miners and the sanitary force in which rocks, clubs, knives, and firearms were used, requiring the force of rural guards to whip them into submission, but not without many injuries on both sides. The mining officials did everything in their power to aid me and to their assistance the successful issue is

bushwacking operations against the Spainards often depended on this source for their drinking water in this section of the island. Malarial infection has always been very common and peculiarly virulent in this part of the island. The sick report of the mining company's employees was largely made up of malarial cases, so the company was very anxious to eradicate the disease. A sanitary organization suitable to the needs of this locality was organized, put in operation, and turned over to the mining company, and it is probable that the good sanitary condition in which we left this section will be maintained and the disease gradually disappear.

Tuberculosis Among Orientals.—The death rate from tuberculosis among the Chinese residents of the United States is 658.5, and among the Japanese 239 per 100,000 living, while among the white population of the country the rate is 173.

ACUTE GONORRHEAL PROSTATITIS.*

By FERD. C. VALENTINE, M.D.,
AND
TERRY M. TOWNSEND, M.D.,
NEW YORK.

A CORRECT understanding of the subject under consideration naturally premises a knowledge of the gross and histological anatomy of the prostate and its conditions in health.

By rectal palpation may be determined the size, consistency, width, and sensitiveness about the interlobular cleft. The size varies in different individuals, generally ranging from one and one-half to two inches in breadth, one to one and one-half inches from base to apex, and from three-fourths to one inch in depth or thickness. Its weight is from six to eight drachms. If the testicles are normal and no diseased condition obtained prior to the examination, the lobes are usually symmetrical. The consistency varies more or less with the sexual exercise of the gland. In those examinations immediately following ejaculation, the elasticity of its structure is less marked. In general, the density is less than that of the cervix uteri and somewhat greater than testicular tissue. The normal gland is always sensitive to a degree on palpation. This is more marked at its apex. The discomfort of palpation does not become pain except in hyperesthetic individuals. The most unpleasant feature of prostatic digitation is the sensation of a foreign body in the rectum, causing a desire to defecate which overshadows whatever other sensations may be produced. The interlobular cleft may vary considerably in width, the two lobes may flare widely apart or they may seem in apposition and still be normal. This cleft has no clinical significance except in prostatic hypertrophy.

Microscopically, the gland is usually of the compound acinous or racemose, but at times tubuloalveolar type. The follicles, or better acini are lined with a number of layers of cuboidal epithelium and the ducts with simple columnar epithelium. In occasional instances the epithelial lining of an acinus may appear stratified, being partly cuboidal and partly columnar; this, however, is exceptional. Corpora amylacea are not rarely present in the acini, some observers claiming them to be more prevalent in different periods of life. They are variously sized, concentrically striated round or oval corpuscles which do not give the reaction of amyloid material, but are undoubtedly colloid in character; they have no known significance. These acini and ducts are divided into compartments by fibrous trabeculæ extending from the capsule inward and are divided from each other by fibrous tissue liberally interspersed with smooth muscle fibers, blood-vessels, non-medullated nerves, and lymphatics.

Comprehension of the character of the normal prostatic secretion is also necessary before considering the inflammatory changes that may occur. The secretion massaged from the gland and examined microscopically contains cuboidal epithelial cells mechanically removed from the acini, occasional corpora amylacea, a scanty number of leucocytes, and a number of small, yellowish corpuscles varying in size, known as lecithin corpuscles. By the addition of a few drops of a one per cent. solution of ammonium phosphate and drying for one-half hour, Charcot-Leyden crystals may be found as yellowish needles or whetstone shaped crystals.

When a gonorrhea of the anterior urethra extends to the posterior division of the canal, acute gonorrheal prostatitis almost invariably follows. Frank reports 100 per cent. of infections of the gland after posterior urethritis, other authors report prostatic infections without even the most transitory symptoms of posterior urethritis, explaining the infection by the anastomosis between the lymphatics, blood-vessels, or a symptomless posterior urethritis. Other students deny this frequency and record from three to eighty per cent. of prostatic infections. Our percentages agree with Frank's and others in claiming invariable infections after posterior urethritis.

This diversity of opinion is doubtless due to different interpretations of what constitutes acute gonorrheal prostatitis. We accept the diagnosis when the microscope shows gonococci in the prostatic secretion, regardless of the clinical appearances or course. The more usual exiting causes of the extension of the infection are omitted or misdirected treatment of apparently uncomplicated clap, horseback or bicycle-riding, disobedience of instructions during treatment, *e.g.* indulgence in drink or coitus, exposure to cold, incorrect or ill-advised urethral instrumentation, reduction of vital resistance.

The pathological varieties of acute gonorrheal prostatitis may be divided into (1) simple catarrhal, incorrectly spoken of as follicular, and (2) diffuse or parenchymatous, which is not infrequently sooner or later complicated by areas of suppuration. In the simple variety the gland is not enlarged or hardened. The acini and ducts are widened and their lumina filled with desquamated epithelium, leucocytes, and small round cells. The submucous fibrous tissue is infiltrated with leucocytes and inflammatory corpuscles. The orifices of the gland ducts emit a straw-colored fluid containing epithelium, lecithin corpuscles, leucocytes, and a scant number of gonococci. This is the follicular prostatitis described by authors.

In a further stage of the inflammation the gland ducts become obstructed by the periglandular infiltration; stagnation of the secretion takes place, and a small follicular abscess may result. This has been termed by Jadassohn "pseudo-abscess" because of its being a collection of pus in a preformed space or lumen. These small abscesses may break through the duct into the ejaculatory duct or through the urethral mucosa directly.

In the second or diffuse or parenchymatous variety of the inflammation, the usual inflammatory changes occur in the whole structure; congestion, serous exudation into the tissues, epithelial desquamation and disintegration. If the inflammation cannot be arrested at this point, the continued bacterial irritation may cause small abscesses to form in the interstitial connective and muscular tissue and in the alveoli. These small pus formations tend to rupture into the ducts, or if in proximity, may coalesce. Many instances are observed after recovery, where a large depression in a lobe is felt, due to this destruction of tissue with its subsequent cicatrization.

Although the tendency of the abscesses is to rupture through the ejaculatory duct and discharge themselves into the urethra, yet they are as prone to follow the plane of least resistance as are abscesses into other parts of the body. Segond (quoted by Wossidlo) found in 140 observations of

*Read, by invitation, before the Georgia Medical Society, Savannah, October 27, 1908.

perforations, 64 were into the urethra, 43 into the rectum, 15 into the perineum, 8 into the ischiorectal fossa, 3 into the inguinal region, 2 into the obturator foramen, 1 into the peritoneal cavity, 1 under the navel, 1 into the ichiatic foramen, 1 beside the false ribs, and 1 into the space of Retzius. When the abscess ruptures through the rectum, perineum, ischiorectal fossa or inguinal region, persistent and obstinate fistulæ result. When they rupture into the other parts mentioned or into Retzius' space, pelvic cellulitis occurs. It is obviously unnecessary to recount the dangers when the pus is poured into the peritoneal cavity. In any event, if the sufferer has not a good resistance he is in danger from septicemia and pyemia. After the subsidence of the acute inflammation, hard nodules may be felt in the gland, due in part to cicatrization following resolution or to unremoved corpuscular infiltrates. In rare instances the inflammation becomes phlegmonous attacking the rectal wall, posterior urethra, and bladder walls before becoming circumscribed.

The symptoms of a beginning simple or catarrhal prostatitis are with difficulty differentiated from a posterior urethritis. The urine may contain the small comma filament described by Fürbringer or may be so purulent that they are invisible. As above indicated and hereinafter elaborated, every posterior urethritis confirms the diagnosis of at least a simple catarrhal prostatitis.

In the diffuse variety of cases the symptomatology is plainer. Dysuria is an early and annoying symptom. The frequency and urgency become marked and the difficulty in emptying the bladder is at times pronounced. The urinary stream may split and dribble, require several seconds to be established, and is preceded, accompanied, and followed by pain. This pain is described to be of a boring character, beginning in the prepubic region and usually extending toward the navel or anus. At other times it may radiate into the glans penis, testicles, or along the inner aspect of the thighs. Temporary and occasionally even absolute urinary retention ensues. Attention has been directed elsewhere* to this cause of retention and methods for its relief submitted. Obstipation, constipation, and ribbon stools are occasional symptoms, due to mechanical interference of the prostatic tumor.

The urethral discharge, if copious, becomes scanty; the urine, if previously purulent, becomes clearer. The latter symptom may be explained by interrupted drainage from the gland. The former symptom is probably due to a transference of the battleground of the bacteria and phagocytes.

The inflammation may be preceded by a chill and subsequent rise of temperature to 100° or 102° F., but this is not constant. We have, in common with many other observers, attended numerous patients who at no time showed elevation of temperature. Malaise, anorexia, and similar constitutional disturbances are constant. Rectal palpation will disclose a large, hard, tense, hot, and quite sensitive tumor filling the rectum. This tumor may be unilateral or bilateral in accordance with the acutely inflamed prostatic area. We have, in numerous instances, been unable to explore the upper segment of the gland because of its size, sensitiveness, and encroachment into the rectal space.

Simple catarrhal inflammation can be diagnosed only by the microscope. If, after free urination and urethral cleansing, the expressed prostatic secretion shows gonococci, a varying number of pus corpulses and prostatic epithelium, the diagnosis is determined. Another certain method of diagnosis is uranalysis. The presence of epithelium from the prostate gland and its ducts in moderate number will be proof positive of the extension of the infection into the gland. Regarding this method of urinary diagnosis, Dr. Louis Heitzmann cannot be given too much credit for his persistent development and practical application of epithelial diagnosis and differentiation. The diagnosis of the diffuse form is never difficult because of the clinical history and the physical findings. The presence of a large sensitive and perhaps fluctuating tumor in the prostatic region of recent origin can mean only acute prostatitis.

The differential diagnosis between tuberculous nodosities and circumscribed spots of prostatic gonorrheal infiltration is not so easy. The clinical history, the presence of tubercle bacilli, the course of the disease, and urinalysis will in most instances clear up the diagnosis. Malignant growths and syphilis must not be overlooked in obscure cases.

Before discussing the treatment of acute gonorrheal prostatitis we will consider the prophylaxis of the complication. Although anterior gonorrhea extends to the posterior urethra in ninety per cent of infections, and although 100 per cent of posterior urethral infections are complicated by prostatitis, yet we may confine the disease to the less severe form of simple catarrhal infection in many cases. Strict adherence to all the sanitary and hygienic directions usually given in acute gonorrhea, regulation of daily habits, perfect action of the emunctories, and regular local treatment should be insisted upon. Careful technique, which is imperative in urethral irrigations, will exclude this treatment from the causative factors of prostatitis.

In simple catarrhal inflammation, massage of the gland twice weekly followed by intravesical irrigations with a silver salt will prove effective. In prolonged cases, the irrigation may be omitted and an instillation of silver nitrate substituted. It is of utmost importance to direct treatment to the prostatic urethra as well as the gland, since the infection is reciprocative between the gland and the urethral mucosa.

In diffuse prostatitis the treatment is more extensive and of greater urgency. If a chill precedes and an elevation of temperature ensues, rest in bed and fluid diet are required. If no fever is present the patient may be allowed to sit about in his room, but active business pursuits are not permissible.

Hot applications promote phagocytosis and favor resolution as in other structures. The rectum should be flooded with copious normal saline solution from 115° to 125° F., according to tolerance every three hours. We may also further the progress of repair by sitz baths of the same temperature and frequency. Pursuant to Wossidlo's suggestion, we have for years used suppositories of codei phosphate, gr. ¼, iodoform gr. ii. in cocoa butter, following each of the rectal douches. If the patient can afford expert nursing service, the Kemp tube is more serviceable than the simple rectal douche. Goldberg has suggested ichthyol irrigations and suppositories, but our uniformly good results with iodoform and codeine in conjunction with the methods above outlined, have given us no reason as yet to try new features. When the prostatic congestion is severe and pro-

*"Vesical Retention of Urine," *Medical News*, June 18, 1904.

longed, leeches may be applied to the perineum. We confess skepticism regarding their value.

Internal treatment is of but slight avail. When constipation is present, one of the cascara preparations acts best. Salines, aloes, etc., seem to induce rectal tenesmus and increase the patient's discomfort. Painful urination may be relieved or ameliorated by the santal preparations. If the microscope shows an ascending infection, hexamethylamine and sodium benzoate āā 0.5 may be given every three hours for their urinary antiseptic effects.

This treatment we heartily commend, because in the past ten years no case of which we have had the complete management has gone to the operating table for evacuation of the pus formation. On the contrary, those cases presenting with marked fluctuation and symptoms of systemic infection requiring prompt drainage had been treated with psychrophores, ice bags, and other methods wholly at variance with the demands of the condition from a pathological viewpoint.

The operative route for evacuation of a prostatic abscess is through the perineum. Rectal incision, rectal puncture, and attempts to rupture the abscess through the urethra by means of pressure with a sound introduced into the bladder belong to a past era and are mentioned only to be condemned. The exposure of the gland is simply accomplished in the following manner: The patient is placed in the lithotomy position, a central perineal incision is made from a point externally corresponding to the bulb to within one-half inch of the sphincter ani. A prerectal crescentic incision is then made connecting the posterior edge of the central perineal incision. The skin and superficial layer of fascia are then dissected off, leaving exposed the bulb and the central perineal tendon. This tendon is then divided and blunt dissection with the finger exposes the rectourethralis, a small slip of muscle extending from the rectum to the bulb. This must be divided to allow the rectum to be detached and freed from the prostatic capsule. At this point the wisdom of the operator will decide whether to introduce a retractor into the posterior urethra and vesical neck to bring the gland nearer the surface. If the bladder is opened to admit the rectractor, subsequent drainage is necessary and will prolong convalescence in addition to the increased risk of vesical infection.

If the abscess cavity can be palpated without intravesical retraction, the surgeon makes an incision through the prostatic capsule into the cavity. This incision should be in a line almost parallel to the urethra, the upper part slightly inclined outward, thus minimizing the number of gland ducts severed. The finger is then inserted into the cavity and any trabeculæ encountered broken down. Frequently small neighboring cavities about to rupture into the larger one can be felt and the necrotic process accelerated by a removal of the retained pus.

Drainage with a wick of iodoform gauze and reapposition of the severed perineal structures complete the operation. The gauze wick may be removed by steps on the first three postoperative days. Hemorrhage will not be troublesome if the surgeon takes due care to make the initial incision in the median perineal raphé and expose to the structures by blunt dissection.

There are enthusiasts who present cured or improved cases of acute gonorrheal prostatitis by means of applications of high frequency currents to the gland. Unfortunately, we have not had the pleasure and profit of examining these cases before and after treatment. Until this method has been more universally and satisfactorily demonstrated, we must persist in what we believe to be correct surgical principles. The injection of vaccines has been of no value in our hands. The number and virulence of the gonococci in the prostatic secretions was unchanged at each microscopic observation.

The prognosis *quod vitam* is good. Regarding a short convalescence from the gonorrhael infection it is always bad. The tendency of the disease to chronicity is marked especially in the diffuse type. It is therefore extremely important that effective and persistent treatment be continued until a cure is obtained, because of possible future recrudescences and to avoid infection of previously normal prostatic lobules.

After repeated attacks of diffuse prostatitis the gland is more or less damaged and its physiological functions limited through loss of tissue in cicatrized areas; therefore, aberrations of its sexual and urinary functions are not uncommon sequelæ.

The frequency of acute gonorrheal prostatitis and the possible local and general results thereof, when this complication is overlooked, seems sufficient justification for its presentation before a body consisting essentially of general practitioners. It is upon them that the diagnosis and treatment of the majority of cases of gonorrhea devolves. Literature on the subject is voluminous and scattered and, as a rule, accessible only to the genitourinary specialist. If we have given a slight satisfactory conspectus thereof, that may aid our colleagues in general practice to successfully meet gonorrheal prostatitis, our object will be attained.

171 West Seventy-first Street.

THE TREATMENT OF DISEASES IN SENILITY.

By I. L. NASCHER, M.D.,

NEW YORK.

The microscope, the germ and the scalpel are driving out the stethoscope, the rale and the pill. Our patient is now a case, an object for original research who might have some undescribed form of bacteria hidden somewhere in his anatomy or who might be a fit subject for a new surgical procedure or a new hyphenated therapy experiment. The old family doctor and his old-fashioned empirical methods have become obsolete, since every organ and tissue of the body has been appropriated by the specialists, and medical treatment has been made subordinate to laboratory research and surgery. Since drug nihilism is the prevailing sentiment of the day, and drug treatment has been largely supplanted by the many new therapies, all still experimental, it requires some hardihood to attempt to resurrect the old methods and advise their use. Yet some of these old methods in the hands of the physicians of a generation ago were often successful where our modern experimental methods fail, and it is but reasonable to assume that their more scientific application based upon our present knowledge will increase their usefulness.

While this should apply to all cases and all classes of diseases, I will consider these old methods only in the strangely neglected senile diseases.

In a recent article on Geriatrics I advanced arguments for considering senility a physiological

entity, and its diseases not as diseases of maturity with senile complications, but as diseases of senility, apart and distinct from maturity. If we accept this view, then we must revise our views concerning the diseases of senility and their treatment, for the senile processes which are now looked upon as pathological processes of maturity must be considered physiological. Instead of attempting to "remove the cause and cure the disease," efforts must be made to retard the senile processes, just as we endeavor to hasten mental and physical development in youth. Every organ and tissue is involved in the senile process, the "Process of Involution," as Canstatt calls it, the altered conditions produce altered functions, the harmonious relations and interactions are maintained with difficulty, they are easily interrupted and not readily restored. In maturity we have the mysterious vital resistance to disease which maintains these harmonious relations, and if they are interrupted it tends to restore or readjust them.

The physician's province in maturity is to remove the cause of such interruption, if it persists, and hasten restoration. He aids nature in bringing about a cure.

In senility the pathological processes act upon organs and tissues that are undergoing an organic change which weakens the power of the vital resistance. It is not within the scope of this paper to discuss the nature of this inherent property of the fundamental cell which we call "vital resistance," and "vital influence." This property manifests itself most strongly during maturity, but it becomes rapidly weaker as the senile changes progress. A senile disease left to itself will not cure itself, but it will hasten decay. The closely allied organs which in maturity will aid a diseased organ and accommodate themselves to changed functional relations, can neither aid nor accommodate themselves to changed conditions in senility. In pneumonia in maturity, for example, increased heart action increases pulmonary circulation in the unaffected part, thereby maintaining proper oxygenation of the blood. If the heart is in a healthy condition it can keep up this rapid pace for days without impairment. In senility the increased heart action hastens its own degeneration. In maturity nature cures; in senility nature kills. In maturity the physician tries to aid nature; in senility he tries to thwart nature and retard the natural senile process which ends in death. In maturity his purpose is to eliminate the cause and restore diseased tissue. In senility his primary aim should be to prevent the immediate cause of death. There are cases where an offending cause persists and can be readily reached and removed as in toxemia from decomposing food waste which has not been voided owing to peristaltic inactivity. Even in such case our measures for removing the cause, cleansing the bowel, should be combined with measures to overcome the subsequent weakness.

Incidental complications, *i.e.* those due to the primary disease, and accidental complications, *i.e.* those not due to the primary disease, are comparitively infrequent in maturity and the incidental complications are generally avoidable and often curable.

Incidental complications appear frequently in senility; are rarely avoidable as they depend upon a hastening of the senile changes, and they generally end in death. Most deaths in senility are due to these secondary diseases, and it is to prevent these that the physician's first efforts should be directed.

In a male fraternal order maintaining rigid entrance examinations, 326 deaths of members over 50 years of age were reported in three months. Of these 86 were reported due to heart disease, angina pectoris, and arterio sclerosis, 60 to diseases of the brain and cord, 43 to diseases of the lungs, 47 to kidney and bladder diseases, 22 to gastrointestinal diseases and diseases of the liver, 21 to cancer, 19 to suicide and accident, 7 to diabetes, 6 to asthenia, and 15 to other causes (acute infections, etc.). It is probable that in the final analysis most cases due to pulmonary, renal and hepatic diseases ended in cardiac exhaustion or paralysis, and most of the cancers and gastro-intestinal diseases ended in general exhaustion. Most of the deaths due to brain troubles probably followed rupture of atheromatous cerebral vessels, as 47 cases were stated to be due to apoplexy, cerebral hemorrhage or paralysis.

It is impossible to say how many of these accidents were produced by vasoconstrictor cardiac stimulants, given to sustain a weak heart without regard to the condition of the cerebral vessels.

The two main causes of death in senile diseases are exhaustion or paralysis of the heart, and asthenia, and these may occur in almost every disease that prevails in senility. There are many other direct causes of death depending upon the nature of the disease, but these two should engage the attention of the physician before any treatment of the disease itself is inaugurated, emergencies naturally excepted.

We must remember that the manifestations of senility may completely mask the symptoms of disease, that the discomfitures incident to the senile manifestations are often much greater than the pains and discomfitures from some grave disease which may be present, that the severity of the symptoms bear no relation to the severity of the disease.

There are few pathological conditions in senility which do not affect the heart and the circulation. As the heart is already weakened, any sudden strain may paralyze it, or a long-continued strain may exhaust it.

It has become a universal practice to give digitalis, both as a heart tonic and a heart stimulant, to prevent weakness and to overcome it. In fatty degeneration, the usual condition of the heart in advanced senility, digitalis may produce cardiac apoplexy or complete rupture, or else rapid exhaustion ending in paralysis. Being a powerful vasoconstrictor, it is dangerous in states accompanied by high arterial tension, hence it should never be given in arteriosclerosis. In aortic insufficiency it may produce spasm of the heart.

Strophanthus has the typical digitalis action upon the heart and raises the blood pressure through the increased force of the contractions, but it has only a mild vasoconstrictor effect. Spartein has no direct influence upon the blood vessels, increases the force and rapidity of the cardiac contractions followed by rapid exhaustion if its use is long continued. Strychnine is an excellent cardiac stimulant for a short time, increasing the functional activity of the heart muscle until its maximum capacity is reached. Further stimulation may cause paralysis or ex-

haustion. Strychnine should be used only as a temporary stimulant, given until the heart responds, then stopped. Caffeine acts like strychnine, but it is neither as powerful nor as rapid, and it can be given for a much longer period. Carbonate of ammonia is the best cardiac stimulant in an emergency. Alcohol is an excellent cardiac stimulant, but as it hastens degenerative processes it should be used only while there is an absolute necessity for cardiac stimulation. For continued use as a heart tonic in senility I have used iodide of arsenic.

In our efforts to sustain the heart in senile disease the choice of drugs depends upon the disease and the condition of the heart and blood-vessels. The contraindications must be considered fully as important as their indications. It should be borne in mind that absorption and assimilation are changed in senility; that salts and alkaloids are rapidly absorbed and vegetable tinctures are absorbed slowly; that digitalis, while the most reliable heart tonic, is slow in action and cumulative.

If the heart and blood-vessels are in good condition at the beginning of an acute disease in senility, digitalis should be given from the onset. If there is atheroma, strophanthus should be given instead. (Its glucoside, strophanthin, is a powerful vasoconstrictor.)

The second main cause of death in diseases of senility is general exhaustion. General asthenia, progressing to the point of complete cessation of nervous activity, is the cause of death in old age uncomplicated by disease. Every form of activity has a moderate limit when the organ or tissue employed is fatigued, and an extreme limit in exhaustion. While fatigue affects only the part employed, exhaustion affects the whole system and demands complete rest, during which recuperation takes place. The power of recuperation is a manifestation of the vital resistance and is weakened during senility, and in disease at this period it may be entirely abolished. A pathological process is a form of preverted activity in an organ or tissue, the part diseased becomes soon fatigued, then exhausted. Unless the recuperative power is great this exhaustion spreads to allied organs whose functions are altered to accommodate themselves to the altered functions of the diseased part, and finally the exhaustion extends to the entire organism. When the vital resistance of the individual is already low, as in senility, exhaustion rapidly follows any intense or extensive pathological process, and with weakened or abolished recuperative powers the exhaustion proceeds to complete cessation of nervous activity in death.

After the physician has taken precautions to prevent exhaustion and paralysis of the heart, his next duty must be to prevent general exhaustion. We have here a similar problem as with the heart. We must try to retard the hastened degenerative processes, maintain vigor and tone, and guard against emergencies.

For the first of these indications our measures are almost entirely hygienic and dietetic. The iodides have been used in arteriosclerosis and fatty degeneration, and while useful here they also favor atrophic changes.

Any physical activity increases waste and weakens the system, therefore active exercise must be avoided. While it is impossible to prevent the senile changes, it is possible to reduce the waste and increase repair by proper dietetic measures. This is especially important in senile disease when waste proceeds more rapidly than normal at that period of life. Remembering the changed digestion, assimilation, metabolism, and elimination of waste tissue, our food should contain a minimum amount of nondigestible, nonnutritious elements, and lime salts. The predigested foods on the market contain so much alcohol that a sufficient amount of them to nourish an individual would also keep him in a state of constant intoxication. Meat juice, peptonized milk, malted milk, malt extracts, eggs, the farinaceous foods, like farina, sago, tapioca, barley, rice, etc., must form the staple articles of diet and the gastric and pancreatic ferments should be added.

It is not possible to secure a diet entirely free from lime salts without introducing greater disadvantages. The foregoing list embraces foods in a concentrated form or leaving little waste, which are readily digested and assimilated, are nourishing and maintain bodily vigor.

It is not necessary to abide by this restricted, concentrated diet with digestive ferments in health, but in disease in senility it is necessary to give as little work as possible to the digestive organs. Aside from nutrition this diet also imparts vigor, thus preventing exhaustion. As a general tonic in senility, not only in disease but in the usual senile debility I would suggest phosphorus in the form of Thompson's solution. I have used this with or without nux vomica for years and have yet to see the first case where ill effects resulted. It has no cumulative action and no depressing reaction, no habit is formed, and its action is permanent. In diseases where there is rapid exhaustion phosphorus and nux vomica or strychnine form a rapid and certain stimulant which will overcome the exhaustion. Caffeine is a good nerve stimulant which will prevent fatigue and exhaustion for a short time. It can be alternated with strychnine, but the two should not be given together except in an emergency. Alcohol, if used continually, will be useless in an emergency and in some forms of exhaustion as from hemorrhage and diarrhea, it is harmful. In pneumonia it is useful from the beginning of the disease, but in an emergency, as in heart failure or danger from exhaustion in that disease, if it has been given before, it is useless then and we must fall back upon the rapidly acting energetic drugs.

If there is no contraindication against digitalis phosphorus, or strychnine, these drugs combined in a liquid mixture should be given in every disease in senility. My favorite prescription is tincture nux vomica 2 drams, tincture digitalis 2 drams, solution of phosphorus (Thompson's) ½ ounce, tincture cardamon comp. 1 ounce, distilled water to make 3 ounces; dose, teaspoonful.

Besides the two main fatal complications, heart failure and exhaustion, almost every disease of senility has some incidental complications which may cause death. In pneumonia, for example, there may be asphyxiation from mucus in the bronchi, which the patient is unable to expel. Hypophosphite of ammonium is a powerful stimulating expectorant useful in this condition, but it should not be employed unless this condition is present. Pulmonary edema is a dangerous complication in senile pneumonia and usually ends in

death from impaired oxygenation of blood and cerebral paralysis. The edema may be prevented by changing the position of the patient frequently. The most frequent causes of this complication being enfeebled heart action and passive pulmonary hyperemia, these conditions should be attended to.

Paralysis of the lung generally occurs without premonition and may supervene upon a mild inflammation with a sound heart. Atropine is the best respiratory stimulant, and being also a cardiac stimulant, it can be used from the beginning in senile pneumonia.

In Bright's disease death usually occurs from cardiac complication, occasionally from uremia or pulmonary edema. Drinking large quantities of water will generally produce a copious diuresis, but in chronic nephritis a more powerful stimulant is needed. If digitalis is not contraindicated by the condition of the heart, it should be used in infusion, preferably in combination with the acetate of potassium. If digitalis cannot be used buchu and juniper will be found serviceable. Aside from drinking large quantities of water to maintain the activity of the kidneys, no renal stimulants should be used until there are indications of renal inaction or perversion.

It is impossible here to consider all the diseases and causes of death in senility. My object in this paper is to call attention to the primary indications in diseases in senility, which should be, not to cure the disease but to prevent death. In maturity incidental complications and the question of diet are secondary to the treatment of the pathological condition. In senility they are of primary importance.

At the Battle of Aspern Napoleon's army opposed the Austrian front and succeeded in driving it back until the powerful Austrian flanks came into action and forced Napoleon to retreat. After the battle of Wagram, Archduke Charles reported that Napoleon began the battle by menacing the Austrian flanks and kept them out of action throughout the battle. Without the assistance of the flanks the Austrian front was defeated. In senility the flanks, the incidental complications, are more dangerous than the front, the primary disease; keep them in check and there will be less difficulty in dealing with the main disease. In treating diseases of senility we may be deceived by apparently urgent symptoms which are merely indicative of the senile processes and which mask mild symptoms of a serious illness. Thus the dyspnea of a chronic emphysema may mask the shallow breathing which would point to other lung involvement, and while we are treating the patient for an incurable emphysema he develops pulmonary edema following a pneumonia which presented no marked symptoms. Such mistakes cannot happen if the physician will discriminate between the clinical value of the manifestions of senility and of the symptoms of disease at that period.

It may be charged that this paper is based mainly upon empirical experience and hence lacks scientific worth. Even with all our laboratory knowledge, with our microscope and scalpel, we have not yet reached the point where empiricism can be cast aside. Until we know the why and how of drug action and can explain the basis of Virchow's dictum that certain substances have an affinity for certain parts of the body, we must be guided by experience in our treatment of disease. So little has been done in the field of geriatrics that until it receives the attention its importance deserves and we know more about the metabolic changes in the period of decline, we must fall back upon empiricism in the treatment of diseases in senility.

EVIDENCE CONTROVERTING ROSENBERGER'S TUBERCULOUS BACTERIEMIA HYPOTHESIS.*

By BOND STOW, A.M., M.D.,

pathologist to metropolitan hospital, new york city.

Last February I met and learned from Dr. Randle C. Rosenberger the technique employed by him in his studies demonstrating his hypothesis that "Tuberculosis in all its forms is a bacteriemia." That method has been fully described and published by him in Vol. cxxxvi No. 2, pages 267-269 of *The American Journal of the Medical Sciences*. I immediately began independent studies upon this question but with the following simplified technique, believing that a more simplified and direct method would produce results more accurate and less liable to adverse criticism.

Procedure in Bedside Cases.—A ligature was placed above the elbow and the arm thoroughly disinfected. Ten c.c. of blood were withdrawn from any prominent vein under strict asepsis. This blood was immediately smeared over the entire surface of two slides that had previously been prepared, as follows: Slides first cleaned in water and soap suds. Then placed in the following solution: Potassium bichromate, 50 grams; water, 200 grams; sulphuric acid, 300 grams, for twenty-four or more hours; then rinsed in distilled tap water and immediately before the smear was made passed several times through the flame.

The smear was then allowed to dry in the air and then fixed by passing several times through the flame. They were then stained with freshly prepared carbol-fuchsin solution and destained with 25 per cent. hydrochloric acid in 95 per cent. alcohol and counterstained with a watery solution of methylene blue. The specimens were now examined direct without use of cover glass. In all cases where acid-alcohol-fast bacilli were present I found them deeply stained and presenting the usual morphology of similar bacilli found in tuberculous sputum (*i.e.* the beaded appearance, uniformly stained, and branching forms). In no case were doubtful or suspicious appearances accepted. Each slide was systematically examined with use of the mechanical stage passing in review hundreds of fields and occupying not less than three hours before it was declared negative.

Results.—Ten incipient cases where positive acid-fast bacilli were found in the sputum, presenting a clinical history of tuberculosis, showed absence of any acid-alcohol-fast bacilli in the blood. Eighteen advanced cases all with positive acid fast bacilli in the sputum showed presence of acid alcohol fast bacilli in the blood in six cases and absence of same in the balance.

Procedure in Autopsy Cases.—All were cases of undoubted advanced peribronchial type of tuberculosis with caseation and cavity formation. The heart

*Read in discussion at stated meeting, May 24, 1909, of the New York County Medical Society.

was tied off from its main blood-vessels and removed with its contained blood. The surface of the right and left ventricle was thoroughly singed with red-hot, flat-bladed knife as well as placed directly in the flame. Each ventricle was opened separately with aseptic knife and the blood thus aseptically procured immediately smeared over surface of slides made aseptic as above. The lungs were removed entire and after drying same as well as possible each lobe was bisected by one cut through its longest diameter with a knife previously passed through the flame.

One of the largest pulmonary veins was then selected, and after allowing the first blood to pass off the blood within the vein was taken with an aseptic platinum spatula and immediately smeared on aseptic slides. Every possible precaution was taken not to touch any of the adjoining tissues, thus avoiding contaminations. The general absence of extraneous bacteria on examination of the slides proved the thoroughness of the work in avoiding contaminations while securing the blood from the pulmonary veins.

RESULTS: ACID, ALCOHOL, FAST BACILLI IN THE BLOOD FROM

Case No.	Left Lung	Right Lung	Left Ventricle	Right Ventricle
1	+	–	–	–
2	+ Sparce; 4 acid fast bacilli in all	–	–	–
3	+	+	–	–
4	+	+	–	+ Plentiful
5	–	–	–	–
6	–	+ One acid fast bacillus?	–	–
7	+	–	–	–
8	+	+	–	–
9	+	+	–	–
10	+	+	–	–
11	+	+	–	+
12	+ Large numbers of acid fast bacilli; extensive phagocytosis.	+ Ditto	+ Sparce	+ Sparce

Remarks.—The results of all the above examinations are at variance with those of Rosenberger and Forsyth* of London, both of whom found acid-fast bacilli in the blood of every case of tuberculosis. Rosenberger and Forsyth, by their methods, laked the blood before staining. I refrained from this procedure, staining the blood directly as smeared and fixed upon the slides. What bearing has this upon our conflicting results? The work of Walter V. Brem upon this subject as published in Vol. LIII, No. 12, of *The Journal of the American Medical Association*, would appear to give the answer. Brem finds that the contamination of distilled water with acid fast bacilli in all laboratories where animals are kept frequently occurs, and that this is a very prolific source of error, particularly when blood smears are laked in such distilled waters before staining for tubercle bacilli. He obtained constantly positive results before eliminating this source of contamination and considers the laking the blood with distilled water (absolutely known to be free from acid-fast bacilli) as the crux of the whole matter. As he states the one result of Rosenberger's animal experiments, "30 guinea pigs showing acid-fast bacilli in blood suspensions while having no tuberculous lesions is strong evidence in favor of contamination rather than of the presence of tubercle bacilli in the circulating blood."

In the technique of my work upon this subject no distilled or tap water was used at all before the staining, and this may account for the differences in Rosenberger and Forsyth's results and mine.

The problem involved is a very difficult and momentous one and much more work will be required upon it before the medical world will be justified in accepting Rosenberger's hypothesis that "Tuberculosis in all its forms is a bacteriemia."

A NEW METHOD OF APPLYING LACTIC ACID BACILLI IN THE TREATMENT OF SUPPURATING WOUNDS.

By W. B. McLAUGHLIN, M.D.,

NEW YORK CITY.

It has been ordained in nature that every animal or plant has its natural enemies, which prey upon it and limit the numerical growth of that species. Darwin has shown that where conditions are particularly favorable for the growth of any animal or plant, sooner or later its natural enemies will come upon the field, and, finding food conditions favorable to them, will grow at the expense of the original inhabitants, the newcomers to be in turn preyed upon by their natural enemies; and so on *ad infinitum* go the kaleidoscopic changes of nature.

From time immemorial, it has been known that the inhabitants of certain parts of Bulgaria and Switzerland are particularly robust and long-lived. We owe to Metchnikoff[1] the brilliant conception that the condition of these people is due to the activity of the lactic acid bacilli, which they habitually ingest with the milk and cheese that forms such a large part of their diet.

Herter[2], Gregoroff[3], Combe[4], and Cohendy[5] worked out this conception and made it of practical value in the treatment of autointoxication. They proved beyond a doubt that abnormal putrefactive processes in the intestine were due to anaërobic bacteria, and that by the judicious feeding of lactic acid bacilli *in milk*, the lactic acid organisms could be acclimated in the intestines and would supplant the anaërobic organisms. It is generally conceded that the destruction of the latter organisms is due *to the production of lactic acid*, but how is not clearly understood. As far back as 1902 Tissier[6] established the fact that the lactic acid bacillus in a saccharine medium would inhibit the growth of putrefactive organisms.

North[7] first suggested the use of lactic acid bacilli as a method of treating infected wounds. He used as a culture medium to grow the organism, a mixture described as follows: "To make one liter, take fresh extract from one pound of lean beef or veal chopped fine, extracted with one liter of water. Dried Witte's peptone, 20 grams; sodium chloride, 5 grams; dextrose, from 10 grams to 40 grams. Make up into broth in the usual way. The reaction is adjusted to the neutral point, using phenolphthalein as an indicator. As stated above, calcium carbonate in lumps is sterilized with the medium."

In this medium he grew Metchnikoff's Bulgarian bacilli to the fullest capacity of the medium, and this growth was used as a local application in the treatment of over 300 inflamed surfaces, including atrophic rhinitis, ethmoiditis, frontal sinusitis, acute rhinitis, hay fever, otitis media, chronic rhinitis, tuberculous sinuses, antrum, gonorrhea, suppurating wounds, peritonitis, cystitis, leucorrhea, Riggs' disease, gonorrheal ophthalmia, diarrhea, conjunctiv-

itis. The applications were made by different physicians in different parts of the country, fifty-six cooperating in the work. Of the result reported in all cases, 225 were improved and in 86 no results were obtained. This exhaustive paper leaves no doubt that the lactic acid bacillus is destined to play an important part in the treatment of infected wounds.

It occurred to me that the one weak point in North's experiment was that the medium which he used had been exhausted by the growth of the bacilli before it was applied to the wound and that better results could be obtained if the bacilli were applied in a medium suitable to their development in the wound.

It is a generally accepted fact that the principal part played by the lactic acid bacilli in the inhibition of the growth of the putrefactive and pathogenic organisms, is due to the production of nascent lactic acid in the wound; if this be true, then the bacilli must exercise a more favorable action when applied in a medium in which they can grow and develop than when applied in a medium in which they have already grown and developed to the full capacity of the medium.

Acting on this idea I prepared a powder consisting of the sterilized and dried solids of skim milk which I incorporated with a dried culture of Metchnikoff's Bulgarian bacilli, care having been exercised in the drying of the culture not to carry the temperature above 101° Fahrenheit. This powder was then used as an ordinary dusting powder on cases of carcinoma, chancroid, purulent ulcers, and ordinary septic wounds. The results have been such as to justify me in the belief stated above, that in order to get the fullest action of lactic acid bacilli, they must be applied in a medium suitable to their growth and development in the wound and that this medium must be capable of undergoing lactic fermentation.

A CASE OF TOTAL OPHTHALMOPLEGIA.

BY FRANCISCO M. FERNANDEZ, M.D.,
HAVANA, CUBA.

OUTSIDE of very few cases of clearly hysterical source, most of the cases of ophthalmoplegia are of organic cause. It is an uncommon affection, and I find it even more so in Cuba. I offer no reason for this.

The case here reported was surely of nuclear origin, that is, it had no superficial cause. The non-superficial ophthalmoplegias, taking as a base of study the nuclei of the various motor nerves of the eye, can be subdivided in three groups, namely, supranuclear, nuclear, and infranuclear, respectively. As just said, the case to be here described did not appear to be of superficial origin.

N. L., negro woman, born in the U. S., about 30 years of age, came for consultation to the clinic of Dr. J. Santos Fernández, on June 1, 1909. She stated that ten days before, on getting up from bed in the morning, she noticed that the right upper eyelid was drooping and that it was impossible to elevate it without the use of the hands. It was not possible to move the right eye in any direction and there was almost complete loss of sight of that eye. From what we could get from her we suspected the possibility of a specific infection, although not clearly. She said that at the time of her present illness, or some days before, she had nausea and vomited some. A year ago she had a numbness of the right side of the face, which later disappeared. At the time of the onset of her present trouble she also noticed some numbness in the same region.

The examination revealed a complete ophthalmoplegia. There was a very pronounced ptosis in the right eye with absolute immobilization of the eye. The pupil of the affected eye was wider than the left, although not dilated to its maximum. There was complete absence of any pupillary reflex. Vision was limited to the perception of light. There was a slight degree of exophthalmus. On the right side of the face there was a zone where the sensation although not entirely abolished was greatly diminished. This zone extended from the right side of the forehead and nose and also invaded the conjunctiva and cornea of the same side. There was a very marked lacrymation.

The ophthalmoscopic examination, made by Dr. J. Santos Fernández and myself, revealed absence of any characteristic sign; the disc of the right eye was entirely the same as the left; both were of small size, but of normal redness. The left eye had perfect vision.

The patient was submitted to an adequate antispecific treatment and was given besides tincture of nox vomica. This treatment was carried on for a week only as after that time the patient did not come back.

This case of total ophthalmoplegia was evidently of nuclear origin, specially as there was complete absence of all traumatic or other peripheral cause. On account of the absence of diabetic or traumatic cause, and of all signs that would lead to suspect a periostitis or the pressure of a tumor, that might by compression give origin to the disease, I did not think it erroneous to ascribe it to syphilis. Unfortunately antisyphilitic treatment was carried out for only a week. This was unfortunate for the patient, for if the case was, as we thought, of syphilitic origin, the prognosis would have been, as in most cases of this origin, favorable.

Schools in the Open Air.—Samuel Bernheim and Louis Dieupart say that it has been demonstrated that all city schools contain a number of pupils who are in the incipient stage of tuberculosis or the pretuberculous stage, being from twelve to seventeen per cent. of all the scholars. Vacation houses at the sea and mountains are only palliative measures, and the few weeks spent there are not enough to bring about a cure. The remedy is to open schools in which the studies and exercises shall all take place out of doors, near the woods, if possible, the pupils only going indoors in stormy weather. These open-air schools have been experimented on in Germany and Lyon, and have given excellent results. The teaching should be especially such as to physically develop the children and should consist of graduated exercises, baths, douches, respiratory gymnastics, and exercises to make them more supple, and should be accompanied by substantial nourishment. This will in a few months transform the feeble child into a strong and rosy child, firm and resistant.

THE INFECTIOUS NATURE OF POLIOMYELITIS.

THE recent epidemic of this disease that has swept through the Brownsville section of the Borough of Brooklyn has furnished opportunities for study that cannot fail to be fruitful in dealing with future visits of this grim enemy of childhood. Dr. Le Grand Kerr has investigated sixty-five cases that he has observed, of which the first fifty-three had occurred in the above-mentioned district, in an area approximately one mile by one mile and a half. In none of the cases had there been any history of direct contact of the children with others that had been infected, and it was probable that a third party had been responsible for carrying the infectious agent. In seven instances the disease had developed in houses in which other cases had already appeared, but in different apartments. In every case the families had visited one another freely. In twenty-three instances cases had occurred among children living in the same block, exclusive of the cases occurring in the same house, and in only nine instances did the families visit one another. In studying the infectious nature of the disease, Kerr places great stress upon the two factors of individual and tissue susceptibility. The former was indicated by the fact that the disease appeared in most instances before the end of the third year of life—in 59 out of 65 cases. The influence of previous disease appeared to be negative. Although there were histories of recent injuries in but four cases, it was possible that either a local injury or a shock to the entire body might favor infection, while the injury of overexertion in the very young could not be estimated. In most of the infants under one year of age, there were slight signs of rickets, while the bony changes occurring as the result of this disease were quite evident in thirty-one of the cases over one year of age. It appeared as if malnutrition, which, affecting the nervous system as well as the rest of the organism, and which is the chief etiological factor in the production of rachitis, had a rôle to play in favoring the individual susceptibility to poliomyelitis. The incidence of this disease during and shortly after prolonged spells of hot and dry weather seemed to be connected in some intimate manner with the depressing and exhausting effects of this weather upon the infantile organism. It was probable that the microbic agent was one of low virulence. This was borne out by the facts that usually only one member of a family was affected, and that the microbe was unfavorably influenced by low temperature or required the aid of heat to give it its power.

As the result of his investigations, Dr. Kerr concludes that acute poliomyelitis is a hematogenous infection with a microbic agent of low virulence, that this infection is engrafted upon a tissue susceptibility acquired through the agencies of local malnutrition, exhaustion, and never impairment, and that the most favoring factor of all is an individual susceptibility over which we have no control.

In connection with these clinical observations, the laboratory investigations recently reported by Drs. Simon Flexner and Paul A. Lewis (*Journal American Medical Association*, November 13, 1909) acquire an added significance. Although Landsteiner and Popper had already succeeded in inoculating monkeys with poliomyelitis, by means of injections of spinal cord from fatal cases of poliomyelitis, Flexner and Lewis have been the first to carry the virus of poliomyelitis successfully through a series of monkeys. In one group of experiments it has been possible so far to transmit the disease through a series of six monkeys, and apparently there is no limit to the number through which it might yet be carried. It is quite obvious that these results will afford opportunities for the study of this disease that cannot fail to produce practical results. The discovery of a curative serum is certainly not a remote possibility.

THE ERADICATION OF PLAGUE FROM SAN FRANCISCO.

To state that plague is entirely eradicated from San Francisco is to state what cannot absolutely be proved; but so far as can be judged from the opinions of those competent to speak with authority the disease does not exist in San Francisco at the present time, and taking into consideration the sanitary condition of the city now, it is not likely to regain a foothold. The manner in which the threatened epidemic has been fought and conquered in the metropolis of the Pacific Coast reads like a chapter from some book of olden time and not like a happening in this material and somewhat prosaic age. The report of the San Francisco Citizens' Health Committee with the account of its work provides, however, fascinating and engrossing reading, and only shows how much sheer energy can accomplish when directed by intelligence.

In May, 1907, plague reappeared in San Francisco, and slowly but surely continued to spread. The distressing feature of the recrudescence, for it is believed to have been a recrudescence and not a reinfection, was that it was no longer a typically Oriental disease, not yet wholly a filth disease. Very few Orientals were affected, almost all the 160 patients, of whom 77 died, being white persons, many of them of a good condition of life, subsisting on generous diet, and dwelling in houses that would commonly be called sanitary. In September, 1907, fifty-five cases of plague existed in San Francisco, and the

city authorities, realizing that the matter had become a national concern, appealed to the Federal Government for help. Surgeon-General Wyman thereupon placed the conduct of the campaign in the hands of Passed Assistant Surgeon Rupert Blue, who, together with Dr. Glennan, had been instrumental in stamping out the epidemic of 1900 in San Francisco.

Blue's brigade commenced operations in the middle of September. They found four infected rats during the remainder of the month, but while the human plague began to decline, probably because the number of fleas was diminishing with cooler weather, rat infection increased. Experience has taught that a rat infection of 2 per cent. means usually a fearful outbreak of plague among human beings. When, therefore, the rat infection in San Francisco approached one and one-half per cent., Blue became convinced that the public must be aroused, and that the whole population must take up arms against rats. A large mass meeting of citizens was held in January, 1908, and at this meeting Blue explained the true nature of the situation, and stated that owing to the wide distribution of rat infection, the difficulties had become greater than the Health Department could cope with. It was consequently necessary that householders should cooperate with the health authorities, should clean their premises, shut off the rats' food supply by keeping all garbage in tightly covered metal cans, and render rats homeless by destroying their nesting places.

The Citizens' Health Committee was then appointed by the Mayor. The committee caused hundreds of meetings to be held, of school children, women's clubs, and representatives of all important lines of trade and industry in the city. It collected $177,512 and disbursed $139,943. It kept four hundred paid inspectors and laborers in the field for several months, trapping and poisoning rats, in addition to the force maintained by the Board of Health and the Federal Government. It purchased nearly $15,000 worth of rat traps, buying cheese for bait in lots of three thousand pounds at a time. It paid out $12,375 in rat bounties. It printed and distributed 700,000 circulars and other forms of literature. It disseminated a widespread knowledge of the mode of plague transmission, and created an interest in sanitation and a general community sentiment in favor of cleanliness that has caused the mortality from contagious illnesses of all descriptions in San Francisco to fall below that of any other large city in the United States, and according to the compiler of the report has left heart disease at the head of the fatal ailments in San Francisco for the year in which the committee was at work.

In conjunction with the Federal, State, and City Health authorities, and through the hearty cooperation of the people themselves, the committee helped to avert a general quarantine which might have set back San Francisco ten years in commerical development, and might have cost it the richest commerce of the Pacific for a generation to come. Under the direction of Dr. Blue and his medical coadjutors the campaign against rats and fleas was carried out in the most thorough manner. In an article of this description there is not scope to explain matters in detail, but the report will provide a valuable textbook for other cities into which plague may enter. The main object was to destroy rats and fleas, which, by the way, in the case of the former, requires the exercise of a considerable amount of ingenuity. The rat is an extremely wary animal and it is not everyone who can destroy rats. A person must be trained in the technique of rat catching and destroying. As for flea eradication, much may be effected in this direction when rats' nests are found, by burning the nests when possible and flooding the holes with a strong solution of carbolic acid. When rats have been destroyed, the next and necessary step is to render every place of human occupation permanently rat proof if the disease is to be really eradicated from an infected city. "This," says Blue, "is not the work of one season alone but should be made a continuous improvement enforced by strong building laws. In other words, the disease must be built out of existence." The work done so capably and effectively in San Francisco has really been done almost as much in the interests of the whole country as in the interests of San Francisco itself. If its citizens had not aroused themselves and fought the plague successfully no one can say how far it might not have spread. San Francisco stood as a bulwark against the rush of the pestilence into the country.

PNEUMOCOCCUS INFECTION SIMULATING INFLUENZA.

With the passage of time and the increase of knowledge of the manifold activities of which the pneumococcus is capable, it is becoming widely accepted that, just as arthritis, chorea, and endocarditis are but manifestations of the rheumatic infection, so pneumonitis, peritonitis, arthritis, otitis, meningitis, and many other apparently local inflammations are but local signs of one general pneumococcus disease. There remains, in fact, scarcely a portion of the human anatomy which has not, at one time or another, been known to be affected by an invasion of this diplococcus. Recently several writers have reported certain general infections and epidemics with the most variegated symptomatology, due to this organism, which at one time was supposed to confine its activities to the pulmonary tissue.

Possibly the most extensive and interesting epidemic of this kind has been reported in the *Münchener medizinische Wochenschrift* for November 2, 1909, by Carl Rose, as occurring in the division for chronic diseases in the Bürgerspital of Strassburg. Within the course of a few days thirty-seven of the eighty-four inmates of the six wards and sixteen of the twenty-six physicians and nurses were taken suddenly ill with what at first appeared to be typical influenza, beginning with a chill and fever, headache, pain on swallowing, pain in the legs and joints, stupor, and malaise. The most characteristic lesion was an exudative pharyngitis, which occurred in all but one of the cases. In those who were young and healthy, as a rule, nothing further happened. In the aged and infirm, however, and those debilitated by chronic disease, the infection ran different and various courses. Ton-

sillitis appeared eighteen times, a dry bronchitis eight times, and a bronchopneumonia four times. Lobar pneumonia was seen in seventeen of the cases, among which occurred the seven fatalities of the epidemic. Three times there was an intense conjunctivitis, twice a marked rhinitis, and once a purulent otitis media and an arthritis. In three instances there was a hemorrhagic nephritis, and in three others a violent diarrhea. The spleen was palpable but twice. In the absence of complications the fever was remittent in quality, lasted ten to twelve days, and subsided by lysis. In the pneumonia cases the fever did not abate until the end of the third or fourth week, and relapses occurred in several instances. In every case, from the sputum, the pharyngeal exudate, the conjunctival secretion, the otitic pus, and the arthritic effusion, the pneumococcus of Fränkel-Weichselbaum was obtained in pure culture, whereas in no case was the Pfeiffer influenza bacillus isolated. Contagiousness was marked. In the first ward attacked nine of the ten patients were infected, and the disease was carried from ward to ward by physicians and supervising nurses, who had recently become infected. The period of incubation varied between twelve and thirty-six hours. Blood cultures were made in every case during the height of the disease, but in two instances only, in cases afterwards fatal, were the organisms grown from the circulating blood.

An epidemic such as here described is difficult to classify according to our present nomenclature. The tendency to confine the word influenza to the infections with Pfeiffer's bacillus is ever growing, and still these cases symptomatically belong to the influenza group. Rose's suggestion that the influenzas be grouped and subdivided into Pfeiffer's influenza, streptococcus influenza, *Micrococcus catarrhalis* influenza, and diplococcus influenza is an unfortunately bulky and inconvenient system. In the absence of a better, however, it may be found necessary for a proper understanding of such infections.

A Family Type of Splenic Anemia.

It is unfortunate that with the present ignorance as to the etiology of the various diseases which may cause anemia with splenic enlargement, and the apparently hopeless variety of names which have been given by different men to the several symptom complexes which are grouped under the name of splenic anemia, more confusion should be added to the present chaos by inflicting upon the medical profession still another type of this disease. Nevertheless, in the *Deutsche medizinische Wochenschrift* for October 7, 1909, Plehn of Berlin calls attention to a class of cases which is sufficiently striking in its peculiarities to warrant especial mention. This condition, first described by Schlagenhaufer, in 1906, is peculiar in that it attacks several members of a family. Of the six reported instances of the disease it occurred singly but twice; two in a family three times, and four in a family once. It is further characterized by a large liver and an immense spleen without ascites, by anemia, occasionally icterus, and a good prognosis. In the cases reported by Plehn three members of one family were affected. The first case to come under his notice was that of a girl of sixteen years who appeared from her size and development to be not over twelve. She was intensely jaundiced; her liver was large, and her spleen was an irregular mass pretty well filling the left half of the abdomen. The hemoglobin varied from twenty to forty per cent. The blood showed many mast cells and nucleated red corpuscles. During the two years that this girl was under observation she improved slowly in strength and color, but her spleen remained unchanged. The second case was in the father of the first, a man sixty-one years of age, who said that as a child he had had a large liver and had been jaundiced. Later, however, he had served through the War of 1870, and had led an active, healthy life, though always somewhat pale. At the time of his examination his spleen reached one and a half hand breadths below the costal border. The third patient, a brother of the first and son of the second, was twenty-six years of age. He had never been ill, though always pale. His hemoglobin was forty-eight per cent., and his spleen extended four finger breadths below the free margin of the ribs. In all of these cases malaria, syphilis, and the usual causes of splenic hypertophy could be excluded, and the fair conclusion seemed to be that these three patients suffered from a family form of splenomegaly remaining through life, and not leading to the fatal termination usual in the better-known forms of splenic anemia.

Spasmodic Stricture of the Esophagus.

Whereas each year anatomical, physiological, or chemical studies lead to the proposal of one or more new theories of the cause of certain of the cases of vomiting of infancy, most of these observations, especially under the recent stimulus of a knowledge of pylorospasm, have been directed to the activities and the chemistry of the stomach, and the esophagus as the cause of vomiting, except with a clear history of the swallowing of a caustic or in the rare cases with a suspicion of diverticulum, has received but scant attention. Last year, however, S. S. Adams presented before the American Pediatric Society the report of a child in which at autopsy a spasmodic stricture of the esophagus was found, and in the *Archives of Pediatrics* for October, 1909, La Fétra describes a similar case diagnosed by him during life. His patient was a baby of sixteen months, who had vomited regularly during or immediately after each feeding since birth. When it was fifteen months of age a stomach tube was passed and an obstruction was met six and one-half inches below the lips. When first seen by La Fétra the child, after taking two ounces of food, which she brought up again mixed with mucus, took the remaining six ounces with apparent ease and comfort. Percussion of the chest before feeding was normal; after feeding there appeared a dullness to the right of the sternum extending from the first to the fourth interspace. A feeding containing bismuth was given and *x*-ray pictures were made. The radiogram taken before feeding was quite normal, that taken afterward showed the shadow of a dilated esophagus ending in a conical pouch opposite the seventh dorsal vertebra. The shadow of the food in the stomach was seen in its normal position, while the space between the pouch and the stomach was quite clear. The history and the radiograms of the case show it to have been one of spastic stricture and consequent dilatation of the esophagus.

Its location, two inches above the stomach, places it in the class of esophagospasm and not cardiospasm. The condition is certainly extremely rare, and its diagnosis during life, as made in this case by La Fétra, is probably unique.

News of the Week.

Red Cross Stamps in Europe.—The United States Post Office Department has issued a statement that the post office authorities of England have notified it that the placing of Red Cross stamps upon letters addressed to Great Britain or South Africa will not be allowed and that no letters arriving at British post offices bearing these stamps will be delivered. The German government has further stated that letters containing these stamps must not have them appear on the face of the letters. Those with stamps on the back, on the contrary, will be delivered. The reason for these rules is the confusion created by the presence of the various stamps.

Endowment of the American Red Cross.—President Taft, as President of the American Red Cross Society, has issued a letter advocating a permanent endowment fund of $2,000,000 for the society, and appointing a committee to raise this fund. The purpose of the endowment is to allow relief in the smaller casualties which do not so much appeal to popular charity and also to enable the society in the case of a great catastrophe to institute relief measures immediately for aid without having to wait for private donations. The present endowment of the society is $119,628, while that of the leading European powers is many times greater: Austria, $2,474,577; Hungary, $968,392; France, $4,471,476; Italy, $1,547,548; Prussia, $4,889,948; other German States, $2,548,265; Japan, $8,080,005.

Tuberculosis in Chicago.—A study of the distribution of tuberculosis in Chicago, made by the Chicago Board of Health, shows that the new cases developed in each 100,000 of the population during the first nine months of the current year were distributed as follows: Business and factory wards, containing many cheap lodging houses and including the "red light" districts, 482; poor residence wards, containing 39 per cent. of the total foreign population of the city, densly populated, 188; fair residence wards, containing 36 per cent. of the total negro population and 24 per cent. of the total foreign population of the city, 158; good residence wards, containing only 14 per cent. of the foreign-born population of the city, 104; semi-suburban wards, outlying wards, sparsely populated, dwellings mostly detached, 87.

Suggestions for Housing Consumptives.—The National Association for the Study and Prevention of Tuberculosis has issued a brief publication embodying the results of recent experience in sanatorium construction. The pamphlet of 87 pages is prepared by Dr. Thomas Spees Carrington. The report covers the construction of most of the modern American sanatoria and is profusely illustrated.

Registration of Births.—The Department of Health of New York has served notices upon the physicians of the city to the effect that as there have been so many instances of failure to report births, as required by law, that the Board of Health has decided to permit physicians to forward to the Department of Health, any time within thirty days from receipt of the notice, such records as they may have overlooked or neglected to file. Thirty days after the receipt of the notice all violations of the law relating to the registration of births will be referred to the Corporation Counsel or District Attorney for action. The letter is dated December 1, 1909.

Early Rearrested.—John R. Early, the man who was detained for many months in Washington last winter as a leper suspect but was declared to be quite healthy at the New York Skin and Cancer Hospital, returned to Washington on December 2 and was promptly rearrested by the Board of Health. The Pension office has cut off his pension on the ground that he is not a leper; the Health officer of Washington has caused his arrest on the ground that he is a leper.

Christian Science Suit.—A suit is being brought against the City of Paterson, N. J., by the husband of a woman who died there recently of tuberculosis. On learning that the woman was under Christian Science treatment the city authorities removed her to a hospital where she died. The husband is now suing the city as having caused his wife's death.

Pellagra in Alabama.—According to State statistics fifty-five persons died of pellagra in Alabama during the first nine months of the present year; of these twenty-two were white and thirty-four negroes.

Smallpox in New York State.—The State Department of Health has been notified of an epidemic of smallpox prevailing in Tonawanda, N. Y.; thirteen cases of the disease having been reported from this town.

Baby Killed by Soothing Syrup.—A case of fatal poisoning of an eight weeks old baby by the excessive use of a soothing syrup was reported in Newark lately. The medicine, which contained morphine and heroin, was given by the mother to quiet a cough.

Poison in a German Hospital.—Five hundred and forty-seven patients in the asylum at Friedrichsberg, near Hamburg, are ill from the effects of poisoned rice which is supposed to have been given to them by one of the employees. Two patients have died from eating the poisoned food and sixty-eight cases are considered hopeless.

Female Nurses in an Insane Asylum.—An experiment is being made in the State Hospital for the Insane at Trenton N. J., of replacing the great majority of the male nurses and attendants by women. It is considered that even violent men patients are more tractable in the hands of a woman than in those of a man and that in consequence of the change there will be a smaller number of accidents and injuries to the patients.

Endowment of a Graduate School of Nursing.—A sum of money, said to be very large, has been presented to the Teachers' College of Columbia University by Mrs. Helen Hartley Jenkins for the endowment of a department for the postgraduate instruction of trained nurses to qualify them for the carrying out of the sociological side of their profession. The chief purpose is to provide especially trained nurses to do house-to-house and settlement nursing among the poor, and give instruction in the theory and practice of hygienic living. The department is to be in the charge of Miss Adelaide Nutting, Professor of Hospital Economics in the Teachers' College.

A Gift for Cancer Research.—Mr. George Crocker, whose death from cancer occurred recently, following that of his wife from the same disease, is reported to have left a large sum to the College of Physicians and Surgeons to be expended in cancer research. The exact amount is not yet known, but it is believed that it will be about $1,500,000.

Consolidation of Medical Institutions.—A petition is to be filed for the consolidation of the Garrettson and Samaritan Hospitals with the medical department of the Temple University of Philadelphia, all being under the charge of the same board of directors.

The Andrew J. McCosh Memorial Committee announced recently that it had received $116,000. The committee has not decided definitely on the memorial, but says that "it seems to be generally accepted that the fund will be expended in erecting the Dr. Andrew J. McCosh Operating Pavilion" on the site of the new Presbyterian Hospital at Sixty-seventh and Sixty-eighth streets and the East River, the site chosen by Dr. McCosh for the hospital.

The New York Post-Graduate Medical School has bought from various owners the properties at 354 Second avenue and 307 to 313 East Twentieth street, a group of five three-story dwellings adjoining its existing quarters on the north and east. The hospital trustees now own the entire block front on the east side of Second avenue between Twentieth and Twenty-first streets with the exception of the southeast corner of Twenty-first street, which is occupied by the Hebrew Charity Building.

The Eastern Maine General Hospital at Bangor is carrying out an extensive series of alterations. The principal changes consist in the addition of a children's ward of sixty beds and a domestic building. The cost of the completed alterations will be $135,000.

A New Convalescent Home will probably be built shortly in New York as the result of the death recently of Mr. John Masterson Burke. His death makes available the sum of $4,000,000, which was put in trust by him in 1902 to be used after his death as a memorial to his mother.

The Harvey Society—The third lecture of the Harvey Society will be delivered by Prof. T. G. Brodie, of the University of Toronto, on Saturday, December 11, 1909, at 8:30 P.M., at the Academy of Medicine. Subject: Renal Activity.

Manhattan Medical Society.—At the next meeting of this society, to be held at Reisenweber's, 58th street and Eighth avenue, on December 11, at 8:30 P.M., Dr. John B. Deaver of Philadelphia will read a paper on "The Use and Abuse of Gastrojejunostomy." An invitation is extended to the medical men of the city to attend this meeting as guests of the society.

The Tri-State Medical Association, comprising the States of Arkansas, Tennessee, and Mississippi, at a meeting held at Memphis, November 18, 1909, elected the following officers: *President*, Dr. J. S. Rawlings of Dancyville, Tenn.; *Vice-presidents*, Drs. W. L. Howard of Greenville, Miss., John L. Jones of Searcy, Ark., and Nicholas Walker of Dyersburg, Tenn.; *Secretary*, Dr. Eugene Rosamond; *Treasurer*, Dr. J. S. Vaughn.

Dr. Daisy M. Arleman-Robinson has been elected a member of the Société Française de Dermatologie et de Syphiligraphie. Dr. Robinson is the first woman upon whom this distinction has been conferred.

Dr. Hyman J. Goldstein of Camden, N. J., has been elected assistant in the nose, throat, and ear, and also in the medical department of the Lebanon Hospital of Philadelphia.

Duke Karl Theodor of Bavaria died on November 30, 1909, at Kreuth, Bavaria. Duke Karl, who was a brother of the late empress of Austria, after starting life as an army officer, took up the study of medicine and was graduated from the University of Munich. Confining himself to ophthalmology the royal physician attained marked prominence in Europe for his scientific attainments and as the author of several works upon his specialty.

Obituary Notes.—Dr. Harlow James Boyd of Alexandria, Miss., was found dead in bed November 21, 1909, aged 56 years. He was a graduate of the Columbus Medical College in 1879 and was a member of the Douglas County Medical Society, the Minnesota State Medical Association, and the American Medical Association.

Dr. J. M. Lanham of Woodruff, S. C., died at his home of apoplexy November 25, 1909. Dr. Lanham was a member of the Spartenburg County Medical Society and the South Carolina Medical Association.

Dr. Theodore Koch of Baraboo, Wis., died November 19, 1909, aged 81 years. He was born in Germany and graduated from the University of Berlin in 1852. He was a member of the Sauk County Medical Society and the State Medical Society of Wisconsin.

Dr. Erasmus D. Leavitt of Butte, Montana, died November 30, aged 67 years. He was a graduate of the Harvard Medical School in 1870. He was a member of the Silver Bow County Medical Society, the Montana State Medical Association, and the American Medical Association.

Dr. Donald G. MacPherson of Brooklyn, N. Y., died at his home November 30, 1909, aged 44 years. He was a graduate of the Long Island College Hospital in 1895.

Dr. Sophia Presley died at Camden, N. J., on November 28, at the age of 65 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1879. She was a member of the Camden County Medical Society, the New Jersey State Medical Society, and the American Medical Association.

Dr. Franklin Hinkle died at Columbia, Pa., on December 2, at the age of 85 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1847. He was a member of the Lancaster County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. George J. Bretz of Brooklyn, N. Y., died November 4, 1909, aged 84 years. The cause of death was accidental gas asphyxiation. Dr. Bretz was a graduate of the Long Island College Hospital in 1864 and a veteran of the Civil War. He had been retired from practice for many years.

Dr. Quincy O. Sutherland of Janesville, Wis., died at his home November 16, 1909, aged 61 years. He was a graduate of the University of Wisconsin in 1871, and the Hahnemann Medical College of Chicago in 1873. He was a member of the Wisconsin State Board of Health.

THE ANTITUBERCULOSIS WAR AND THE RED CROSS CHRISTMAS STAMP.

By S. ADOLPHUS KNOPF, M.D.,
PROFESSOR OF PHTHISIOTHERAPY AT THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL.

Last fall it was my privilege to address the two Red Cross branches—one in Brooklyn and one in New York—pleading with them to help in the antituberculosis war through the aid of a Red Cross Christmas stamp. I published the two addresses in the form of an article in the *New York Medical Journal* of November 28, 1908. I know that hundreds of others, nay, even thousands, have also pleaded, and perhaps more eloquently and more successfully than I, but this shall not prevent me from pleading again for this holy cause, particularly since I have been honored by the officers of the American National Red Cross with an invitation to do so.

The history of the Red Cross is known to most people. It owes its origin to the feeling of sympathy awakened throughout Europe by the suffering occasioned by the Crimean War. The object of the Red Cross Society is in the main to mitigate the evils inseparable from war. All the civilized nations of the world have branches of this truly international association. Founded in Geneva in 1863, it is now not quite fifty years old, but what a glorious work it has done! Throughout the many bloody wars of the last half century the Red Cross servants were truly the ministering angels who lessened suffering and saved countless lives. And not only in wars, but also in other disasters such as floods, earthquakes, mining and railroad accidents, fires, and pestilences, a great army of Red Cross soldiers is forever present to ameliorate conditions, dress the wounded, nurse the sick, feed the hungry, and improve sanitation so as to limit the fatalities as much as may be possible. The heroism of the Red Cross workers, both men and women, has never been surpassed by the gallantry of the bravest soldiers.

Now, this great association has undertaken to fight the most formidable enemy of mankind; one which unfortunately cannot be met openly in battle; one which, by its insidiousness and because it is unseen and unrecognized by the naked eye, is all the more dangerous and difficult to combat. There are probably at this moment 500,000 people in the United States suffering from tuberculosis in one form or another, and 1,000,000 school children who are probably destined to die of tuberculosis before they reach the age of eighteen, and yet modern medical science has demonstrated beyond a shadow of a doubt that tuberculosis is a preventable and curable disease. Its prevention depends upon bettering the hygiene of the masses and improving their living conditions, on the early recognition of the disease, and on the suppression of all centers of infection arising from advanced cases. This is to be accomplished not by cruel isolation and treating the unfortunate consumptive as an outcast, but by removing the consumptive poor to special hospitals where they will be kindly treated and the utmost care exercised to improve their condition and at the same time minimize the danger of infecting others. The home of the conscientious, well-to-do consumptive, in the advanced stages, can often be arranged so that there is really no danger of contagion.

The cure of the tuberculous depends upon the early recognition of the disease and the timely treatment in well arranged sanitary homes or in special institutions, sanatoria, hospitals, or camps, and there is urgent need for such institutions in nearly every State of the Union. Of course, for the tuberculous children we must have many open-air schools and children's sanatoria; and for the tuberculous adult, cured or sufficiently improved to do some work, we must have agricultural or horticultural colonies or other means to give him outdoor occupation.

Unfortunately, tuberculosis is a disease which is most prevalent among the poor, and after what has been said I need not explain any further that in order to prevent and cure tuberculosis in our own beloved country, we need a great deal of money. All the skill of the physician and devotion of the nurses are of no avail when the tuberculous patient lacks the means to buy good food, cannot afford to live in a sanitary home, have proper clothing, or rest when rest is his only salvation. The patient's anxiety for those depending upon him must also be removed. The wife or children, the aged father or mother deprived of their supporter, must be cared for. Tranquillity of mind is as essential to the cure of tuberculosis as all other factors. To do all this, I say again, we need money, much money.

Fortunately, this country is rich and it does not lack in philanthropy and brotherly love, and I know that this appeal which is now going out from the Red Cross will not be in vain. It will give opportunity to the humblest of the humble, to the richest among the rich, to help in this great, good, and holy cause of saving lives, making tuberculous children into strong and healthy citizens, the curable consumptives into breadwinners for their families, and rendering the hopelessly ill consumptive comfortable and happy as far as it is in human power to do.

The whole nation will reap the benefit of a successful war against tuberculosis, and this benefit will not only be sanitary and moral, but even financial, for every restored breadwinner and healthy citizen is an addition to the wealth of the nation.

But let us put aside for a moment the financial aspect. Christmastide is not a season when we calculate on returns for what we give. We find pleasure and delight in giving, in making others happy, and surely here is a splendid opportunity to do this. Let each one buy as many stamps as he can; tell the little children that every penny they can spare for stamps will help to save a little child's life, and although they may not see the little sufferer and receive direct thanks, they as well as the adults can rest assured that their gifts will be appreciated and the unknown donor remembered in the grateful prayers of some tuberculous invalid.

The 1909 Red Cross Christmas stamp is not good for postage. It will not carry any kind of mail, but any kind of mail will carry it. The use of the beautiful Red Cross stamp, carrying Christmas and New Year's greetings, gives an excellent opportunity to everyone to help the antituberculosis cause according to his means. The layman will thus be the coworker of the physician, a true brother and helper. He who makes his Christmas offering by the purchase of as many of these stamps as he can afford to buy will surely feel the season's joy all the more, knowing that through his participation in this work somewhere some consumptive sufferer has been helped, some dark home made brighter, some little child saved.

Correspondence.

OSLER'S CLIMATIC ERRORS.

To the Editor of the Medical Record.

Sir:—In the latest (seventh) edition of Osler's "Practice of Medicine," just issued, there are some statements relative to the effects of sunshine in tuberculosis, which show how difficult if not impossible it is to establish newly discovered facts which reverse old methods of treatment. The history of medicine is a long, grewsome account of the rejection of new ideas until the men who conceive them become authorities themselves. Jenner was opposed by every physician over forty when he announced the facts as to vaccination. Semmelweis was forbidden to teach the infectiousness of puerperal fever, and Oliver Wendell Holmes was vilified for hinting that obstetricians carried the contagion. Bodington was driven out of practice in 1840 for establishing the first modern sanatorium for the outdoor treatment of tuberculosis. Koch, Lister, and Pasteur were treated with much indignity, and the same old disgraceful business will keep up so long as physicians are human, but when they become so superhuman as to retain youthful mental traits until they die of senility we may expect new facts to be instantly recognized at full value. It is therefore perfectly natural that, though it is now fifteen years since von Schmedel proved that skin pigments were evolved to exclude the destructive short rays of light, he is still ignored, as was Darwin for twenty years by the very universities which now scramble to honor him.

Osler mentions the damage done by administering too much mercury to syphilitics, and he would be horrified if he were quoted as advising that no mercury be given in that infection; yet that is the very mistake he has made as to the effects of excessive light in tuberculosis. On page 355 of his work he says: "Major Woodruff believes that sunshine may be hurtful, and he has collected statistics to show that tuberculosis is more prevalent and more fatal among the dark races, who live where the sun shines the brightest."

The statistics show the opposite to be the case, and the published facts prove that light in moderation is beneficial, but in excess is as harmful as too much mercury in syphilis. Instead of the dark races being more susceptible in light countries, the light races are. The last 44 cases of tuberculosis investigation in the Philippines among European types by Dr. Percy D. Jones are as follows: Marked blonds, 12; blonds, 14; medium types, 9; brunets, 9; marked brunets, 0. Osler continues: "The point is one of interest, but I do not think the case against the sun is made out." Of course, it isn't—nor is the case against mercury in syphilis, but the case against excess is abundantly proved in each. Numerous careful observers have shown that excess of sunlight is highly injurious to consumptives, particularly the blonds, and Osler is sadly in error. Even Knopf, the eminent New York expert, says that too much sunshine is or may be harmful.

As to the requirements of a suitable climate, Osler says they are "a pure atmosphere, an equable temperature, not subject to rapid variations, and a maximum amount of sunshine." Not knowing what is meant by a "pure atmosphere" and being under the impression that the atmosphere was "pure" in all climates, that item cannot be discussed, but it is curious and amazing that on the very same page he says: "The Adirondack cure has become of late years quite famous." The Adirondacks are notorious for inequable temperature, rapid changes, and the minimum of sunshine. The amazing part of all this business is that he mentions approvingly warm, moist climates, like Florida, which have been abandoned as tuberculosis resorts because so fatal. The cures in England are made in spite of, or by reason of, a cloudiness many times that of Florida. Indeed, there is an increasing volume of favorable reports from places like Scotland and Norway and our northwest coast, which are the cloudiest on earth. Here in the Philippines we have Osler's ideal climate, "pure atmosphere, an equable temperature, not subject to rapid variations, and a maximum amount of sunshine," yet tuberculosis in European types is so appallingly rapid that the patients die unless shipped home at once; and, moreover, if detected soon enough they have good chances for cure in places having inequable temperature, with rapid variations and a minimum of sunshine. Instead of the case against excessive sunlight being not proved, it seems to be accepted more and more, not only in tuberculosis but also in other diseases. Jacobi of New York, in discussing the management of pneumonia at the 1909 meeting of the American Climatological Association, mentions the fact that there must be "no excess of light" (*Boston Medical and Surgical Journal*, September 9, 1909). Even the *British Medical Journal*, which is so provincial in its discussions of American medical progress and has said contemptuous things against the new facts as to excessive light, now (August 21, 1909) gives space to an article by Wilfred Watkins-Pitchford indicating that even the poor light of the British Islands may be a contributory preliminary cause of cancer and advocating opaque clothing as a preventive. Hyde of Chicago proved years ago that excessive light was a decided factor in skin cancers in migrated types insufficiently pigmented for their new climate. If he had had the supreme advantages of British citizenship perhaps the *British Medical Journal* would have enlightened its readers years ago. Even the London *Journal of Tropical Medicine* published an adverse article and then ignored this matter so vital in the tropics until Sambon of the London School of Tropical Medicine invented an opaque cloth to use in lieu of the native's skin pigments. It does seem that, although protection from excessive light is now one of the primary practical matters of every-day hygiene all over the Oriental tropics, it will require the proverbial twenty years to convince the rank and file of the medical profession further north. In India the matter is accepted as settled, and the northern third of that land has the same latitude and climate as the southern third of the United States. Protection from excessive light is therefore essential to the welfare of Americans, particularly those in the South and sunny West, and we must be wary of the customs which grew up under the protection of the mists and clouds of the British Islands.

Charles E. Woodruff, M.D.

Manila, P. I.

ARE DOCTORS DERELICT?

To the Editor of the Medical Record:

Sir:—Food for thought by members of the medical profession was furnished in an incident which occurred in the recent annual meeting of the Medical Society of the County of New York. About four hundred members were present. The committee on public health reported that so few subjects of consequence had been brought before it for consideration that but one meeting had been held during the year. One member of the society, and only one, arose to remark that if the health of the metropolis had reached such a state of perfection that there was nothing left worthy of the attention of the public health committee there was cause for congratulation. But since this happy state of things could scarcely be said to exist, perhaps the committee had better be dissolved. The medical profession in this day and land is accustomed to congratulate itself and to receive praise because in its zeal for the public welfare it constantly strives to prevent those human ills which furnish its members with their means of livelihood. And in great measure this is true. But while striving with concerted zeal in certain directions is it not strangely apathetic in many matters of pressing importance?

Let a family of tubercle bacilli set up housekeeping in a hospitable lung and sooner or later their progeny will be targets for the artillery of a great medical and humanitarian army recruited expressly for the purpose of giving them battle. But let the intruding germs select a joint or gland in which to sojourn *en route* to the same lung and they will attract but individual interest.

Laboratory pioneers are working with microscope and test tube against the typhoid bacillus, seeking to perfect immunizing or curative sera, while it is left to the lay government at Washington and to such lay organizations as the New York Merchants' Association to spread the propaganda of the extermination of the typhoid-carrying house fly. Meanwhile the physician too often fails to interpose barriers to the flight of this insect from unmentionable haunts to the patient's dinner table.

The rank and file of the medical profession stand with a scalpel in one hand and a morphine pill in the other, pitifully impotent weapons in the fight

against cancer, while leaders in research institutions are exhausting every effort to solve the puzzle of this pest's existence. Meanwhile is it not the duty of every mother's son amongst that rank and file to work with all his available resources for the ability to make an early diagnosis of cancer, since in our present state of knowledge early excision gives the best hope for cure?

Medical organizations whose aim is the prevention of venereal diseases languish for lack of interest and support among the profession at large, but surgeons on every side are cutting out infected organs while the lay world wonders at the progress of modern surgery.

The primal problem of diet—what and how to eat—is of but languid interest to the majority of physicians, who overlook the fact that many of their patients use their mouths as funnels, while it is left to a layman with the necessary public spirit, money, and brains to teach the world how to eat properly. The medical man seeks for a pound of cure for intestinal fermentation, overlooking the ounce of prevention to be found in the proper mouth treatment of food.

These instances of apathy or inconsistency amongst the medical profession might be added to, but perhaps they may suffice to give us pause and lead us to consider whether we are not derelict to our sacred obligations. We should seek to perfect ourselves in order to instruct the public in those things which they ought to know. The moment we shirk our responsibility as teachers in matters of public and private health, a host of charlatans and patent-medicine vendors stand ready to take up the task. To be heard and heeded we should stand united and be ready to teach through our organized representative bodies as well as privately at the bedside. And when we unite to do our full duty to our brethren great will be the results for good.

William S. Thomas, M.D.
New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ANNUAL MEETING R.C.S.—FITZPATRICK LECTURES ON GREEK MEDICINE—SCLERODERMA—OXALURIA—METROPOLITAN HOSPITAL—AMPUTATION FOR X-RAYS INJURY—SLEEPING SICKNESS—OBITUARY.

London, November 19, 1909

Yesterday was held the twenty-fifth annual meeting of the Royal College of Surgeons—to be precise, the meeting of Fellows and Members—as the college existed long previously, but it was only twenty-five years ago that the council agreed to hold this meeting. The president, Mr. Butlin, took the chair, presented the report of the council, and made a few remarks on its contents, referring to the work of the year and to the valuable addition to the museum of the odontological collection of the Royal Society of Medicine. Afterwards the usual protest on behalf of members took place in the form of a resolution affirming the desirability of admitting them to representation on the council. This was carried, as it has often been, and, as one remarked to me, constituted the "annual farcical performance." The council regards itself as the college and cares nothing for members after it gets their entrance money. A further resolution urged the council to impress on the Government the necessity of amending the Midwives Act in order to provide remuneration for professional services rendered under the Act.

In his Fitzpatrick lecture on Greek medicine at the College of Physicians, Sir Clifford Allbutt put forward a defense of the character and teaching of Asclepiades which has often been traduced by incompetent scribblers. The pathway to knowledge had often been, said the lecturer, the pathway to persecution. It was so with Roger Bacon, who was represented only last year as a buffoon in the historical school of his own university. This was an instance of the difficulty of knowing the real character of a man, and this difficulty must be vastly greater in the case of a man who flourished thousands of years ago. Asclepiades occupied a cardinal place in the history of medicine, notwithstanding the broken lights in which he stood. He suffered from the irresponsible invectives of Pliny and later critics. His popularity in Rome was attributed to the gentler means he employed in the richer classes, but these means (baths, diet, etc.) were not concessions to the luxurious, but the results of the newer knowledge he had acquired in Alexandria. He came to Rome for no time-serving purpose, but inspired by a doctrine which seemed to be revolutionary and therefore he had to fight against a powerful array of conservative forces. Sir Clifford extolled the value of the work of Asclepiades as an experimenter who insisted on the impossibility of making two or more experiments under absolutely identical conditions.

There was a good show of cases at the Royal (Clinical Section) on Friday. One of scleroderma was brought by Drs. Rolleston and Carpenter in a woman of 30 who had felt pain and numbness in the hands and slightly in her feet in 1895. First seen in 1899, she then had scleroderma of face, hands, and feet, which had since advanced in some parts and disappeared in others. Attacks of local syncope and asphyxia were also stated to have occurred. She now presents a face affected all over; around the mouth the skin is puckered so as to diminish the oral opening; hands claw-like, phalanges atrophied, with small curved nails.

Dr. T. D. Savill showed a case affecting the extremities in a woman of 56 who had had attacks of angioneurotic edema at intervals through most of her life, but which ceased two and a half years ago when her hands and feet began to get hard and stiff. The scleroderma progressed and the joints became affected. No treatment had been of use. Dr. Galloway remarked that he had found massage of value if persevered in. Dr. Herringham mentioned a case in which death had occurred most unexpectedly and suddenly. He was inclined to think the deeper structures might be affected in a way comparable to myositis ossificans. Dr. Rolleston said the disease could hardly be called a progressive one, as spontaneous recovery might occur. Dr. Savill believed it was a toxoangioneurosis and the position of the lesion at the extremities allied it to Reynaud's disease. Nothing was known of such a toxin, but we do not know much about internal secretions, in which direction we might perhaps in future find some explanation.

In the Medical Section Dr. Robert Maguire had an interesting paper, on oxaluria, in which he related a case carefully observed with a view of tracing the connection between the urinary deposit and the dyspepsia associated with it. The acid phosphate of sodium in the urine has to be allowed for in estimating the oxalic acid, as it retains a certain amount of calcium oxalate. This seems to have suggested to Dr. Maguire that a calculus might be partly dissolved or at least to some degree disintegrated by adding acid phosphate to the urine. He consequently proceeded to find out whether this salt given by the mouth was excreted unchanged in the urine. He found by analysis that it was, and therefore gave it to the extent of two ounces a day dissolved in 100 ounces of distilled water. In six weeks the symptoms had disappeared, though it was practically certain that no calculus had been passed *per urethram*. He considered that it had been dissolved, but to assure himself of the possibility of such a result, experimented *in vitro*. He made an apparatus by which to pass 45 to 50 ounces of fluid at blood heat over a calculus in twenty-four hours. With this he caused a fluid representing the urine, plus the acid phosphate, to drip over an oxalate stone taken from the bladder by a surgical colleague. It weighed 0.48 gram. After six weeks the weight had fallen to 0.08, and consisted mostly of a uric acid. This nucleus was treated by hydrochloric acid and somewhat decreased.

On the strength of these experiments it was proposed to treat calcium oxalate deposits by acid phosphate of sodium in order to prevent the formation of stone, and it was claimed that even after a renal calculus had been formed it might perhaps be so far dissolved as to pass easily through the ureter and out by the urethra. Dr. Bruce remarked that the paper was of no little clinical importance. Dr. Robert Hutchinson distinguished the theoretical and practical points put forward. Personally, he was sceptical of the oxaluria symptom complex, and there were obscure factors which would require consideration. The effect of a long course of sodium acid phosphate would be to increase the acidity of the urine, and there was a tendency in stone cases for oxalic acid and uric acid to alternate. The author had referred to this, and seemed to think it might be possible to clear away the calcium oxalate and then treat the uric acid; but the difficulty of knowing when to make the change in treatment seemed insuperable. Dr. B. Overy believed that citrates of sodium and calcium acted as solvents of oxalates Dr. J. Anderson related a case of irregularly shaped stones in the kidney detected by *x*-rays and

removed by operation. Dr. Tirard thought the case related by Dr Maguire might have been disintegration rather than solution of the stone, so that further observations would be required on the question whether one could by treatment dissolve calculi in the urinary passages. He had used acid phosphate of soda with a view to its aperient action and to change the composition of the urine. If the acid phosphate could be used to diminish the size of, or entirely dissolve an oxalic calculus, Dr. Maguire's observations would be found a great advance. In one of the cases he must admit that the evidence was almost conclusive.

The Metropolitan Hospital, which has been closed for repairs and alterations since last June, was reopened on Monday. A sum of £10,500 has been expended. It seems a large sum, and some of the items might give pause to economists, but it is said that all were needed. There are new research laboratories, electric, *x*-ray, high-frequency installations, and the operating theater has been entirely remodelled and brought up to date. The drainage system has been relaid. The committee are still asking for money, as only £6,500 has been received for the work, and they also want, as soon as possible, to provide a nurses' home.

A further operation was performed on Sunday on Mr. H. W. Cox, who as a pioneer in *x*-ray experimentation lost a finger of his left hand in the early days. Last February three more of the fingers of his left hand were removed, but the disease was not arrested, and now the arm has been amputated above the elbow by Mr. Gould.

The "Sleeping Sickness Bureau" of the Royal Society will shortly publish a work on trypanosomiasis, containing the papers on the subject issued up to April last and references to work on tsetse flies. Major Thimm has the matter in hand, and hopes to make the bibliography complete as regards trypanosomiasis in both man and animals. The book is to be issued at the net price of 4s., which is calculated to cover only the cost of printing.

Dublin mourns the loss of Sir William Thomson, who died in the evening of Saturday (13th), aged 66. He was of Scottish extraction, but his life was passed almost entirely in Ireland. He was a student of Richmond Hospital and the old Queen's University, which afterward became the Royal University of Ireland. He graduated B.A., B.Ch., and M.D., 1872, and took the F.B.C.S.I. in 1874. While a student he became connected with the press, and was for a time on the staff of a daily paper. When he began practice he soon became a leading consulting surgeon, and in due course filled most important posts in that sphere, including surgeon to his old hospital and the various offices of the College of Surgeons up to the presidency. He was surgeon to Queen Victoria and honorary surgeon to King Edward, surgeon to the Lord Lieutenant, examiner to his university, his college, and the army medical department, secretary of the Royal Academy of Medicine, and a representative on the General Medical Council. He was knighted in 1897, and in 1900 made a Companion of the Bath as a small acknowledgment of his services as surgeon to the Irish hospital in the South African war. In 1870 he took the prize of the Royal University of Ireland for his thesis. Later he wrote on the surgery of the arteries of the urinary organs, on which he was a leading authority, and he contributed freely to journals and societies, as well as to the Transactions of the Academy, of which he was editor.

Lieutenant-Colonel F. J. Crawford, M.D., I.M.S., has died from pneumonia on his way to India, and was buried at sea. He was for a long time a Fellow of Madras University, and had had the principal share in drawing up the new Madras code. Colonel Crawford had only recently been gazetted principal of the Madras Medical College.

The death is announced of Dr. William James Russell, V.P.R.S., in his 80th year, formerly lecturer on chemistry at St. Bartholomew's Hospital. Dr. Russell was president of the Institute of Chemistry from 1803 to 1806, and became vice-president of the Royal Society in 1890.

Another death to note is that of Dr. Michael Castenada, consulting physician to the Italian Hospital in London, also to the Italian and Spanish embassies and consulates. He was a University College student, and took theM.B., London, 1857. Two years later he joined the College of Physicians. He was a Knight of the Order of the Crown of Italy, and of Charles III of Spain.

OUR LETTER FROM THE PHILIPPINES

(From Our Regular Correspondent.)

A PLAGUE OF FLIES AND ITS SUPPRESSION—THE VALUE OF SANITARY SUPERVISION IN CHOLERA VISITATIONS—HYPERTONIC SALT SOLUTION IN CHOLERA—MANILA MEDICAL MEETING—PREVALENCE OF THE HOOKWORM—PERSONALS.

Manila, P. I., October 25, 1909.

Recently flies became very troublesome in the public markets of Manila, more especially in the meat stalls thereof. A regular campaign was started against these pests, which has apparently ended in complete success, although it may be well to reserve judgment upon this last point, because it is no uncommon experience for flies to appear in great swarms in Manila and then to disappear as suddenly as they came. In this instance solutions of formaldehyde in 1-500 strength were put into shallow dishes like plates, and these were placed about the markets where the flies were most numerous. It was found that the flies were exceedingly fond of the mixture and as a result of partaking thereof they soon died in enormous numbers. The streets near the markets and other places in the vicinity where they might breed were sprinkled with kerosene. The street sweepings, which are much used in filling in lowlands, were treated with crude petroleum, then covered with lime, and upon this there was placed clean earth to a depth of at least eight inches, instead of four, as heretofore. There was soon a marked diminution in the number of flies and apparently their breeding has been successfully prevented.

The reduction in the number of flies was also a most important matter, in view of the presence of cholera in the city, and no doubt has been a considerable factor in preventing its spread. The cholera situation in the Philippines has remained about the same as for the month of September. In Manila there have been about eighteen cases per week. The disease has been kept under good control in practically everywhere in the provinces. One thing, however, has been very noticeable, and that is that at such places at which active measures were not taken to combat an outbreak, the number of cases increased in an alarming manner. During the week an instance of this kind occurred at Balanga in the province of Bataan, the daily number of cases reaching 16. An investigation showed that the sanitary inspectors placed in charge were incompetent. These were replaced and in three days the daily number of cases was reduced to four. These results are ascribed to disinfecting a number of suspicious wells; compelling the washing of hands in carbolic solution before entering a public market and strict isolation of the sick.

In view of the very favorable results reported by Leonard Rogers of the treatment of cholera cases in India with hypertonic salt solution, it was determined to give this treatment a trial at the San Lazaro Cholera Hospital in Manila. Accordingly, of the last 20 cases of cholera admitted each alternate case was treated with hypertonic salt solution and the remainder with physiological salt solution. Intravenous transfusion was used in all cases. It is of interest to observe that the mortality of the ten cases of each series was 50 per cent., thus there was no difference in the death rate between the two methods of treatment. The low mortality of approximately 20 per cent., which was reported by Rogers, could evidently not be repeated here. Careful chemical examinations of the blood of these cases, made by Prof. Hans Aaron of the Philippine Medical School, also failed to confirm the findings of Rogers.

The regular monthly meeting of the Manila Medical Society was held at the Philippine Medical School on the evening of October 4 at 8:30 p. m. Papers were read on obstetrical subjects by Drs. Calderon and Quirino and one, entitled "Some Observations on Cholera," by Allan J. McLaughlin, M.D. The author held that, in spite of the difficulty of tracing the source of the infection, particularly in Manila during the beginning of the outbreak, pertinent investigation seldom failed to connect the case with some previous case by direct contact, or mechanically and indirectly by the means of foodstuff, which had been infected by an active cholera carrier. He also invited particular attention to the fact that many of the cases in children that were reported as meningitis proved upon autopsy to be cholera, and that it was no doubt due to such cases occurring in the past that the disease had been spread.

On September 30 the examination of practically all

of the residents of Las Pinas, in the province of Rizal, and from nearby villages, numbering in all over 6,000 people, was completed. Of this number 24.2 per cent. males and 8.06 per cent. females were found to be infected with hookworm, or an average of 16.13 per cent. of the population were found to be hosts of this health-destroying parasite. As these persons were all practically living upon a sandy soil, it is interesting to observe that the number of infections was 6.13 per cent. higher than among the residents of Tay-Tay, who live upon a clay soil.

Major Charles E. Woodruff of the Medical Corps of the U. S. A. has been detailed as the Medical Officer in charge on the Island of Corregidor, at the mouth of Manila Bay, where extensive fortification construction is being done.

Major Roderic P. O'Connor of the Medical Corps, U. S. A., who has been stationed at Manila and Fort McKinley during the past two years, and who has been the army specialist in eye work, sailed for the United States on October 15, having completed his tour of duty in the islands.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 25, 1909.

Variations in the Posterior Horn of the Lateral Ventricle, with Notes on Their Development and Suggestions as to Their Clinical Significance.—E. J. Curran emphasizes the following points: (1) In a large percentage of brains the tip of the posterior horn is cut off from communication with the rest of the ventricle by a constriction and adhesion about the calcar avis. (2) In a large percentage of cases the adhesion of the walls is complete throughout the occipital lobe, making the short horn, so-called. The ependyma, however, remains on the two adherent walls. (3) In a large percentage of cases the tip has a very narrow communication with the rest of the ventricle, but on account of the thinness of surrounding structures any pressure is likely to close this aqueduct and produce a temporary disturbance in the circulation of the cerebrospinal fluid. (4) Any of the above conditions would cause similar circulatory disturbances. (5) When the posterior horn is particularly or entirely closed by adhesion of the walls any increase of internal pressure would tend to break through the adhesions and re-establish the normal posterior horn. Such a result might cause pain. (6) That the calcarine fissure and the cerebellum, which also modify the shape of the posterior horn, are developing rapidly about the time of appearance of convulsions in children is an interesting coincidence. (7) The large proportion of anomalies in the posterior horns of brains from institutions is significant. (8) In all cases the ventricle should extend far into the occipital lobe, and traces of its having been there at one time during development are always found there. (9) The relationship of the optic radiation and other structures to the posterior horn are important in connection with the causes of temporary scotoma, migrains, and possibly other conditions. (10) The condition of the posterior horn should always be examined in cases of obscure cerebral disease or mental disorders.

Chemical Examination of the Feces of Infants and Children After Gastroenterostomy.—The object of F. B. Talbot's study was to determine whether or not gastroenterostomy performed on babies with benign pyloric stenosis modified the digestion of starches, fats, and proteins. He states his findings in tabulated form. The weights of the stools of these patients, after operation, all come within normal limits. All the children are perfectly well and have gained weight satisfactorily. The chemical and microscopical examination of these stools show that in the majority of cases the digestion is normal. It is evident that if there be any indigestion it is more probably of the fat and that chemically and microscopically there are no signs of marked protein or fat indigestion.

New York Medical Journal, November 27, 1909.

Postepileptic Albuminuria.—J. F. Munson, resident pathologist at the Craig Colony at Sonyea, presents the following as his conclusion from the observation of a large number of cases: (1) Postepileptic albuminuria is found in about 20 per cent. of all patients examined in a fairly large series of cases. Men are much more frequently affected than women, and severe seizures are more likely to cause the condition than are mild attacks. (2) The condition is not constant in the same individual. (3) Control urines show the absence of albumin at times when the effect of seizures may be eliminated. (4) The presence of albumin is almost invariably associated with the finding of casts, sometimes in great numbers and variety. They persist longer than the albumin, but may also be found in the interparoxysmal period in the absence of albumin. (5) The first appearance of albumin may be at any time within the first two hours after the attack and it may not disappear till the fourth day. (6) Physical examinations are not fruitful of diagnostic results, except that a few slight heart findings are noted. The blood pressures are in some of the cases elevated. (7) In a series of cases of death in or shortly after seizures congestion of the kidneys is almost constantly found, with albumin in the lumen of the tubules. There is also a good deal of chronic change. It seems probable from the evidence submitted that there is renal congestion following many severe and some mild seizures. This alone is sufficient to account for the albuminuria, and perhaps for some of the casts. There are not a few cases in which signs of chronic nephritis are present on histological examination. It seems to the present writer that we have to deal with a condition which has its origin in the congestion following or associated, at any rate, with the seizure and it does not seem an unfair presumption to assume that some of the chronic changes are due to the congestion so often repeated.

Biology as the Basis of Infant Feeding.—H. D. Chapin says that there is a lack of uniformity in pediatric literature in regard to the standards advocated in infant feeding. Some authorities lay stress on the calorimetric method; others prefer that of percentage composition of food, while still others advocate various chemical manipulation of the milk or lay stress upon adjusting the proportions of casein and albumen in the food. Finally some place their dependence on peptonization. No one can always achieve success by adherence to any one of these plans. The proper plan is that suggested by biology in which the main points to be considered are a sufficient supply of proteins to permit the production of new tissue, enough energy foods to supply the necessary amounts of energy to carry on the vital processes, and the adaptation of the form of the food to suit the peculiarities of the individual infant. This reduces all plans to a scientific basis to which all may conform. Neither biochemistry nor any other single plan can solve the question of the best producing power of food, nor can the quantitative manipulation of the ingredients of various milks form alone a broad enough basis for scientific infant feeding. They may all be employed, but must be subordinated to their proper place by biology. This science, however, will always put the emphasis on growth as the largest factor in early life. It likewise for the first time in the history of this question considers the developmental as well as the nutritive functions of milk in connection with the evolution of the particular digestive tract it is intended to serve. Along this same line it will incidentally show how far various milks are interchangeable and suggest methods of making them so.

The Relation of Tuberculosis to Infant Mortality.—C. F. von Pirquet comments on the various forms in which this disease manifests itself in the early months of life and comments on various statistics which seem to show that when these are carefully taken different cities and localities present practically the same results. Tuberculosis is very seldom inherited, but we find in nearly every case of tuberculosis in infants that there has been another person in the environment who has had open tuberculosis. Whether the infection is directly through droplets containing bacilli, which are coughed out by the infected person and then breathed in by the child, or taken in from the dust of the room in which sputa have been dried out, is still a doubtful question. In comparison with the danger from these open cases that from infected milk is rather small. Still all infected cows ought to be removed from farms that supply milk for babies. Prevention is better than cure. The following method has been successfully tried: All cattle in one farm are tested with tuberculin, those which do not react are sent to a new farm. All calves which are born of tuberculous mothers are immediately separated from the mother and receive milk only after it has been boiled. Afterward they are sent to the healthy farm. After a number of years there are

no more cattle in the infected farm and no tuberculous cases in the new farm. We cannot apply that system to humanity, except in orphan asylums, because it would interfere with our family relations, but still we can make people understand that a nursling is no toy for its relatives, and especially sick relatives, and that parents who have an open tuberculosis do better to apply as much caution as possible in kissing the child or coughing in its presence.

The Significance of Posture in Obstetrics.—This subject is considered in detail by A. F. King, who lays stress on the following points: As we have created the necessity of ligating the umbilical cord by cutting it with a sharp instrument, so have we created the necessity of manual version (with all its dangers of infection and uterine rupture) by depriving the woman of the natural method of rectification by thigh pressure in the squatting or kneeling posture. So again we find it necessary to apply forceps in hundreds of cases when the head is on the perineum, a necessity artificially created by ourselves, by our having deprived the woman of the power of thigh pressure, by which she could be readily delivered, had we not kept her in the recumbent posture. Again, if pressure of the heel over the great sacrosciatic foramen is nature's method of securing rotation, then the necessities of vaginal manipulation and difficult application of forceps have been artificially created by ourselves, in that, by keeping the woman recumbent, we have deprived her of the mechanical influence of heel pressure in promoting the desired rotation. We find it necessary or desirable to press upon or manipulate the uterus after delivery, in a particular way, to promote its contraction, to expedite delivery of the placenta, and prevent hemorrhage. But observe that we have necessitated this plan artificially by keeping the woman upon her back and taking away her child and consigning it to the nurse. Had the conventions of civilization and of modern obstetrics not interfered, the natural mother would have cared for her newborn child in the natural way. See then what would happen: The mother, if recumbent, would rise to a sitting, kneeling, or possibly standing posture; she would lean forward and take the child in her arms, and with maternal affection fold it to her bosom. The unbroken cord would be long enough, counting the length of the infant's body from the navel to the mouth, to allow the child to suckle the nipple, which it would immediately proceed to do, thus producing reflex uterine contractions, which would be further strengthened by the pressure of the child's weight and the perpetual motion of its feet, upon the fundus uteri. The uterus would also receive additional pressure upon the fundus, from the weight of the abdominal organs pushed down upon it by the woman leaning forward, and thus lessening the space between her diaphragm and pelvis. In prehistoric times this was the method—the natural method—by which uterine contraction, placental expulsion, and the prevention of hemorrhage were secured.

Journal of the American Medical Association, November 27, 1909.

Salt-free Diet in Nephritis.—V. C. Vaughan says that the following points seem fairly well established: "1. Urea and uric acid are not important constituents of the urine so far as their toxicity is concerned. I mean to say that neither of these can be regarded as the active agent in the causation of those symptoms that result from failure to function on the part of the kidney. 2. About 85 per cent. of the toxcity of the urine is due to its inorganic constituents, the most toxic of which is potassium chloride. 3. There are present in normal urine certain organic poisons, the nature of which has not yet been ascertained. 4. Although the inorganic constituents, notably potassium chloride, are markedly poisonous, they cannot be regarded as standing in a direct causal relation to that complex of symptoms which we designate as uremia. A small fraction of a grain of potassium chloride, as I have frequently demonstrated, injected into a ventricle of the brain of an animal, may cause prompt death, but neither the symptoms nor the postmortem findings are those of uremia." He is confident that withholding salts does not touch the real cause of uremia. It seems possible that the inorganic salts of normal urine and its organic constituents may neutralize each other partly. At least it has been repeatedly found that the ash of urine is decidedly more toxic than the whole urine, and he thinks that there is room for more research on this point. There is evidence also that an absolutely ash-free diet may disturb the health and this also needs further study. In dogs, long-continued feeding of salt-free diet materially reduces the acidity of the gastric juice, and it has been repeatedly shown that there is a minimum of salt content in the living tissues below which it is impossible to go. Single organic salts may be more poisonous than a combination, and, therefore, there is reason for suspecting that the inorganic constituents of the urine may neutralize each other. Vaughan shows that salt retention is not proved to be the cause of nephritis or of its edema, and it seems to him that the greatest good is to be secured by restricting salt in the diet of patients who may be called prenephritics, and there are many of this kind; he is in the habit of advising such individuals to have their food prepared without the addition of salt. He is positive that we eat too much highly salted food. With unsalted food we drink less and the kidneys are relieved of excessive work; otherwise, he has never been satisfied that he has seen any benefit in any form of nephritis in denying the patient the satisfaction of his thirst. It seems good sense to limit the consumption of food in nephritis, so far as possible without distress to the patient.

Hypertension in Nephritis.—J. H. Musser says the causes of hypertension in nephritis are unknown. The theories are based mainly on deductions from clinical experience and to a lesser extent on experiment. Neither of these, however, give us conclusive evidence, but each in its way points to a reaction of some chemical substance influencing the circulation. What that is, we do not know. Clinically we notice that hypertension and heart hypertrophy are encountered in that group of diseases in which uremia is also apt to occur, while both fail in practically all other types. In other words, hypertension like uremia is a sign of renal insufficiency. It naturally suggests itself that the poisons are the same, or if different are due to the same causes. If the same it may be possible to conceive that in small quantities it affects the vasomotor apparatus and in larger ones exerts its action on the nervous system. In support of this chemical theory it is frequently observed that the degree of the uremic manifestation has close relation with the blood pressure and that true uremia rarely occurs without hypertension. The effect of diet is also suggestive. Rich protein diet seems to increase tension in nephritis and makes the condition worse. All this probably means a retention of the products of nitrogenous metabolism and possibly of the undetermined nitrogen. The increase of these substances in the blood in the renal diseases, in which the uremia occurs, suggests not only that they may be the cause of uremia and include also the substance causing increased tension. Another view, which he thinks may be dismissed briefly, is that which connects hypertension with an internal secretion of the kidney. Little evidence has been brought forward in its support. Another closely related theory which he also considers inadequately supported by the facts is that which connects adrenalin or similar substances with the hypertension. More evidence must be accumulated before a definite opinion in its favor is adopted. The almost constant presence of arteriosclerosis with hypertension in chronic interstitial nephritis is one of the chief difficulties in explaining the hypertension. It is still a question which is the primary condition, though the view that the kidney is secondarily affected seems to be gaining ground. The renal disease following infectious diseases, in which the hypertension appears to be primary and the heart hypertrophy and arteriosclerosis secondary, throws some light on this subject. The hypertension of scarlatina is of special interest, since it comes on very early and at an age when arteriosclerosis can be ruled out. The only explanation which can be offered is increased peripheral resistance, a contraction of arterial terminations as a result of some chemical influence. The association of glomerular lesions with hypertension is also of interest, and this has been emphasized by Schmidt and Loeb. This is an important field for investigation and experiments definitely show that the high pressure associated with glomerular lesions cannot be explained by the older theory of loss of vascular territory in the kidney. Loeb offers the following hypothesis: "Since the renal activity varies directly with the blood supply, lesions of the glomeruli would limit local vasodilation. When the renal activity demands more than the local conditions allow, the stimulus goes beyond the kidney and there is exerted reflexly a splanchnic contraction which leads to an increased systemic tension and then an increased flow of blood through the glomeruli." This explanation, Musser says, brings out prominently the fact that hypertension, whatever its cause, is essentially a conservative process, its object being to favor the maximum functioning power of the kidneys. All the theories except the one of vicarious renal secretion bring us back to the chemical or retention hypothesis.

The Management of Uremia.—E. F. Wells says that in making a diagnosis of chronic interstital nephritis the physician should give his attention to the prophylaxis of uremia. He should inform the patient of the nature of the disease, give a tactful prognosis and directions as to proper diet and general regimen. The diet should be individualized and arranged so as to maintain nutritive equilibrium as fully as possible with the smallest amount of protein and carbohydrate foods. The liquids should be adjusted from time to time so as to help the elimination of waste materials and the regimen should consider residence, clothing, occupation, exercise, etc. Extraordinary care should be taken to avoid infectious disease. The physician should keep closely in touch with his patient, using modern methods of examination, and the patient should consult his physician promptly on the advent of any significant symptom, a list of which should be given to him. Wells does not believe in the probability of uremia occurring without such premonitions as can be detected by an alert observer. As is well known, the blood pressure is abnormally high in these cases. It can be reduced by various medicines, but ordinarily the high tension is conservative and should not be interfered with. In some cases, however, the rise is so rapid as to threaten danger to the weakened vessels, and in this case Wells advises artificial reduction by free bloodletting in urgent cases. In less urgent ones the slower methods may be used. The circulatory balance is seldom fully restored when once lost. Not infrequently circulatory insufficiency follows an acute infection or other depressing influences, without the patient experiencing the extreme tension above referred to. The part played by edema in the production of uremia is important, and Wells thinks special consideration should be accorded to its management in every case of nephritis. He recommends the following treatment from his experience, which, however, may be varied to suit individual needs: During the first day the diet should consist of thin gruels, cream and water, vegetable soups, tea, coffee, cocoa, water, and carbonated waters. From these there should be omitted the gruels on the second and soups on the third day; during the fourth and fifth days very little should be taken; on the sixth day the soups should be replaced and on the seventh day the gruels; later the ordinary careful dietary of the nephritic should be gradually restored. Every night of the first three days the patient takes 10 grains of mercurial mass, in two recently made pills of 5 grains each, followed by an efficient sulphate of magnesium saline purge in the morning. Beginning on the fourth morning, after free action of the saline, there is given 1/30 grain pure elaterin hourly for three doses; 1/24 grain every two hours for three doses; finally, 1/18 grain every three hours until ten or twelve copious watery bowel movements have been induced. During the last series of doses the intervals may well be p. r. n., or as specially directed. Subsequent to the discontinuance of the medicine there will be several more of the liquid evacuations. The elaterin must be pure, and it is preferably given in powder, with sugar of milk and finely powdered ammoniated glycyrrhizin. During the time the elaterin is being given the patient should remain in bed, using the pan. He should be informed of the abdominal distress, nausea, and vomiting which the drug sometimes induces. Without giving reasons for the opinion Wells is sure that, if satisfactory results are to be secured, it will be well to follow closely the spirit of the suggestions in regard to diet, medicine, and general regimen as detailed. He thinks that this treatment will usually drain a large amount of serum through the bowels, and during the period of alvine drain, renal activity is much reduced, but later becomes greatly increased both in quantity and urea content. In some unsatisfactory cases this fails and the edema continues. The other symptoms also subside to the great relief of the patient, but the full benefit is not experienced until about six weeks, and may continue for a long time. Careful medical management will augment the good effects of this treatment and properly directed exercise to keep up cellular activity will be advisable.

Militia Field Work.—F. W. Hendley says that the medical officers and the hospital corps have not been able to utilize recent maneuvers to any great extent on account of the smallness of their numbers. Using the statistics of Ohio, which are most available to him, he finds that the law authorizes for a total of 8,376 men, only 53 medical officers, and 236 hospital corps men, not enough to man two hospitals and two ambulance companies properly according to regulations, leaving out of consideration entirely all regiments and other organizations. In the special camps of instruction for medical officers, such as were established this year for the first time, separate and distinct from the maneuver camps, the medical corps had an opportunity to obtain such instruction but at a cost of doing their work twice over, once in the field with the militia and once in the special camp. Altogether only 170 medical officers out of the 700 or more in the United States attended these schools of instruction this first year, but those that were there were unanimous in expressing their appreciation of the benefits derived, and it can be taken for granted, he thinks, that such schools in the future will be crowded to their capacity. He gives the program of work as observed by him in the camp at Sparta, Wisconsin, where one of these schools was located, and makes the following recommendations for the future: "1. Medical officers should be increased 50 per cent. and the hospital corps 100 per cent 2. Training in field service should be provided for the medical corps and the hospital corps. 3. A progressive course of training, covering six months or more, should be provided, to be completed by attendance at a camp school of instruction. 4. Attendance at such school should be permitted only to those who attain proficiency in the preliminary work. 5. The retaining of a commission as a medical officer should be dependent on participation in such systematic course of instruction. 6. Medical officers in states not represented this year should at the next similar opportunity insist on their rights, and not allow their portion of the available fund be given to their state team at Camp Perry, as occurred in one State in the Northwest this year."

The Lancet, November 20, 1909.

Influenza with Marked Cerebral Symptoms.—H. V. Dillon records the case of a young man of 20 years whom he found in a semi-conscious condition, teeth clenched, face cyanotic, and breathing stertorous. Heart action was tumultuous, occasionally intermittent, 100 per minute. Temperature was 101° F. It was possible to rouse him partially. He was given stimulants, and under treatment gradually resumed his usual mental state, which was of a reserved type. Three days later he was again cyanotic and seemed scorbutic. The lung bases showed symptoms of congestion. The temperature fluctuated between 97° and 102°, as has been noticed in influenza and other microbic diseases when they affect the nervous centers. He was given quinine and an expectorant and gradually built up with good food. The author considers the case worth recording on account of the unusual cerebral symptoms. Prior to these the patient had complained of slight coryza resembling an ordinary cold. His cyanotic condition was congenital, as was also the cardiac irregularity, and he was a subject whom the invasion of microbic disease would be likely to affect more seriously than another having a greater constitutional resisting power.

Sporadic Elephantiasis.—Case reported by H. Barber, whose patient was a woman of 65 years, whose symptoms had come on without apparent cause eight months before. The legs began to swell and become painful on standing. They were stiff and heavy and the seat of cramp-like pains at night. A full description of the case when first seen is given. Treatment was practically without effect. Elastic bandages and massage improved her walking powers. The case is reported because sporadic occurrence of this condition apart from filarial infection is rare. The author found no evidences of pelvic tumor or enlarged glands. Recurrent attacks of an inflammatory nature in the lymphatics usually cause much pain and fairly pronounced constitutional symptoms. In this case the swelling preceded any pain and the constitutional symptoms were very slight, absence of fever being noticeable. The blood was twice examined for filaria, but with negative result. Another noteworthy feature was the complete absence of the lesion in the feet, considering the marked lesion in the legs.

Streptococcal Infection in Diphtheria.—The observations of D. M. Mathieson were made in the course of an epidemic of 80 cases treated in hospital. In 9 cases streptococcal invasion of the throat was found in the course of the disease. The author refers to the work of Sevestre and Martin, who have described certain phenomena occurring about the thirteenth day of the disease. These consist of an eruption, scarlatiniform or erythematous, albuminuria, joint pains, and constitutional disturbance. These were so marked as to suggest a new disease with an incubation period of 13 days. From frequently finding streptococci in the throat cultures of their patients and similar symptoms in pure streptococcus throats, they decided that this organism was probably the one to blame in diphtheria. The following is a brief summary of the author's seven cases in which the "thirteenth day" phenomena were observed. (a) Streptococcal cases: (1) Punctate erythema plus albuminuria; (2) sore throat plus joint pains and rise of temperature (100.8° F.); (3) otor-

rhea; (4) punctate erythema, and (5) punctate erythema plus rise of temperature (99.4° F). (b) Non-streptococcal cases: (1) erythema multiforme and (2) punctate erythema plus rise of temperature (99.3° F.).

British Medical Journal, November 20, 1909

Relapse in Scarlet Fever.—J. W. Fox comments on certain conditions which may be mistaken for scarlet fever. One is measles and particularly German measles, in which the error reveals itself in about 18 days after admission to hospital. Another condition is one produced by food poisoning. Here we have a scarlet rash followed by some fever and a sore throat, but this is never followed by the regular complications of the true fever and the desquamation if any is different. It often arises in several members of the same family at the same time. Some of the cases find their way into hospital wards and contract the true disease. A third form is the following: A patient is admitted with true scarlet fever, which runs a typical course. Yet sometimes after the nephritis the rash reappears, the patient is again acutely ill, the tongue repeals and he seems in every way to have another attack of the disease. Nephritis never redevelops. Are these true relapses; are we dealing with two distinct diseases; are the symptoms of the relapse nephritic or are they due to a pyogenic dermatitis? Sometimes the nephritis is wanting in the primary attack, but appears in the secondary. The author has never met a practitioner who remembers having seen a relapse of any other exanthem. He gives no answer to his own inquiries.

A Method of Intestinal Drainage.—M. Mamourian's method consists in the utilization of the Murphy button with a yard of soft rubber tubing. A purse-string suture of silk is passed around one end of the tube, the male or female half of the button is introduced into the lumen and the head tightened so as to grip the neck of the button. Next a segment of the distended bowel is clamped and a linear purse-string suture inserted. The gut is incised, the other half of the button placed in position and finally the two sections of the instrument are united in the usual way. The anastomosis between the bowel and tube is complete and on removing the clamp there is no leakage and the fecal contents pass out of the tube into a jar well away from the field of operation. The purse-string suture on the bowel need be secured only by a temporary knot so that the suture may be tightened and the incision instantaneously closed after the withdrawal of the button, the bowel being reclamped before the button is removed. If one opening does not give sufficient drainage, the process can be repeated with as many coils as desired or a piece of tubing can be passed up into the bowel and the intestines "milked." The method is, perhaps, more serviceable in cases which require immediate colotomy. The button remains in place four days or so, during which time there is no necessity to inspect the wound. When it comes away, the peritoneal cavity is completely shut off and the wound partially healed. An illustrative case is described.

Lymphangioplasty for Solid Edema.—A. B. Mitchell relates the history of a young man who had severe erysipelas of the face followed by solid edema of both eyelids. Artificial lymphatics of sterilized silk threads were introduced into the subcutaneous tissue. Two short curved incisions, half an inch long, were made into the edematous tissues, a similar incision was made at the outer edge of the orbit and another one down on the cheek below the thickening. The skin below this last incision was freely separated by a blunt director so as to leave a loose pouch into which the lower end of the thread could be dropped. A round needle threaded with sterile silk was then introduced through the incision in the upper lid and brought out through the incision in the orbital margin and the thread drawn through till its upper end, which was knotted (to prevent it becoming dislodged by facial movements), lay buried in the swollen orbital tissue. The needle was again introduced, carried along under the fascia of the cheek and brought out at the lower incision. The thread was now cut, leaving enough to drop into the pouch already prepared by the separation of the skin. A second thread was then introduced in the same way so as to drain the lower lid. The small incisions were sealed with benzoin and collodion. In the recent case the result was very satisfactory and the threads were in position nearly two years later.

Berliner klinische Wochenschrift, November 8, 1909.

Is Cholera a Nitrite Poisoning?—Hyman Van der Bergh and Gutterink call attention to Emmerich's theory that the symptoms of cholera were produced by the nitrites formed in the intestines by the activity of the cholera vibrio. They studied some of the recent cases in Rotterdam from this viewpoint by the spectroscopic examination of the blood familiar to them through their work on "enterogenous cyanosis," in one form of which the cyanosis is due to methemoglobinemia from absorption of nitrites from the intestines and upon dogs poisoned with nitrites. In the cases of cholera studied there was neither methemoglobin nor a trace of nitrites found in the blood.

Münchener medizinische Wochenschrift, November 2 and 9, 1909.

Pathology and Occurrence of Acquired Diverticula of the Appendix.—Konjetzny says that diverticula of the vermiform appendix must be divided into the noninflammatory and the inflammatory. The noninflammatory diverticula occur along the mesenteric attachment at the sites of the foramena of the vessels, and are merely invaginations of the mucous membrane into these openings, which have become dilated. The theories as to the cause of these vary, but the author does not believe that they are the result of local inflammations. The inflammatory diverticula are usually the results of small intramural abscesses. Such abscesses are not at all rare in association with acute appendicitis. The author found two defects of the appendicular wall in the case of a child of ten, each defect, one of which had perforated, holding the end of a bristle. Such cases teach that while foreign bodies rarely cause appendicitis, they may cause serious pathological lesions of the organ. Intramural abscesses may cause diverticula in three different ways. If the abscess is not progressive and does not perforate, it may be absorbed and the cavity be replaced by scar tissue. As this contracts it pulls the mucous membrane outward and thus forms a diverticulum varying in size according to the extent of the original abscess. This is especially deep if adhesions have been formed outside, and if the internal pressure is increased by an acute inflammation. Usually, however, the intramural abscesses do not heal, but perforate either through the mucous membrane or the serosa. If the perforation is through the serosa there are usually preformed adhesions. Thus even a slight increase of intraappendical pressure will bulge the mucous membrane outward to fill the empty abscess cavity. When the abscess perforates internally it may be through a very small opening which allows the otherwise intact mucous membrane to prolapse and later to regenerate around the walls of the cavity where lacking, or the entire mucous membrane over the abscess may be destroyed, in which case the defect may be very deep and have to be covered by invasion of mucous membrane from its edges. Over such diverticula the epithelium is thin and usually cuboidal. These diverticula are of clinical interest in that an inflammation keeping up in them may cause prolongation of the symptoms, they may be the cause of a recurrence, and they are a likely site of perforation. If the perforation occurs along the mesenteric edge it may cause phlegmon of the mesentery.

The Antitrypsin Content of the Serum in Psychoses.—Jach in consideration of the increased antitrypsin content of the blood serum in certain severe corporeal diseases and the close relationship between bodily and mental conditions investigated a series of patients with various mental disturbances as to the antitrypsin in their blood they included dementia precox patients, epileptics, idiots, and paralytics. The technique of Meyers was used. From his investigations he concluded that in a majority of the psychoses there occurred an increase in the antitrypsin content of the blood serum, that the increase was especially marked in paralytics, and that treatment with arsenophenyl glucin seemed to have a favorable influence upon the antitrypsin content of the paralytics.

Examination of the Cerebrospinal Fluid in Trypanosomiasis in the Dog.—Apelt calls attention to the symptoms occurring in men infected with *Trypanosoma gambiensis*, which closely resemble those of dementia paralytica, mental weakness, stupor, loss of memory, ptosis, general tremor, and aphasias. Spielmeyer has shown that dogs infected with trypanosomes show spinal cord degenerations closely resembling those found in the parasyphilitic diseases. Other cerebral lesions were found resembling those of tertiary syphilis. The clinical course of the disease and mode of infection also resembled syphilis. From these Spielmeyer stated that syphilis and trypanosomiasis must belong to one group of diseases. As it had been shown that in paresis, tabes, and syphilis of the central nervous system globulin occurred in the cerebrospinal fluid in 100 per cent. of the cases, the author investi-

gated the cerebrospinal fluid of six dogs which had been inoculated with trypanosomes to see if this relation to syphilis held also. He found that four to six weeks after injection the lumbar fluid shows a pathological increase of cell and protein elements (globulin and nucleoalbumin). Whereas the increase of the cells occurred in proportion to the progress of the disease, a similar progressive increase of globulin was not shown. Nevertheless, the unquestioned increase in globulin gives a further basis for Spielmeyer's theory of the relation of trypanosomiasis and syphilis.

Tuberculin Vaseline for the Conjunctival Reaction in Practice.—Wolff-Eisner says that in practice among ophthalmologists salves are preferable to drops, on account of the difficulty of keeping the latter sterile and the longer time the medicament remains in contact with the conjunctiva. For these reasons he has made a 1 and 2 per cent. tuberculin vaseline ointment for the ophthalmotuberculin test. Such an ointment remained active and sterile for nine weeks in summer in a common ointment jar. This gives it a great advantage over the watery solutions. Its longer time in contact with the conjunctiva makes it a much more delicate and accurate test than the usual Calmette test.

Systemic Lymphadenitis in German Measles.—Hamberger and Schey call attention to the glandular changes in German measles as observed by them in a recent epidemic. Though the posterior cervical enlargement has been mentioned by several writers, in many of the text books it has been entirely omitted. One or two authors have reported isolated cases with axillary or inguinal enlargements. To avoid the danger of error from glandular enlargements due to local causes the authors observed not only those ill with the disease but carefully studied children who had been exposed. This showed not only that changes in the glands occurred but that they appeared in the prodromal stage of the disease, several days before the rash came out. The adenitis at times was marked and the children were occasionally brought to the clinic for that alone. The glandular swellings were not confined to the neck, but involved the entire lymphatic system.

A Case of Banti's Disease.—Arthur Müller reports a case of Banti's disease in a boy of seventeen years, who made a good recovery after splenectomy. The case was of interest as the nitrogen metabolism was studied before and after the operation and found at both times to be normal. In this the case disagrees with that of Umler, who stated as the result of his observations that abnormal nitrogen catabolism was pathognomonic of Banti's disease.

Action of Canadian Hemp.—Kraemer states that the fluid extract of apocynum cannabinum acts through its glucocide apocynin and affects the heart similarly to digitalis. It is a cardiac stimulant and diuretic in doses of fifteen drops three times a day, though some prefer smaller doses—three to five drops—as being effectual without upsetting the digestive tract. The author reports a case of myocarditis with edema and ascites which had not responded to twelve of the common diuretics, but cleared up in a day under Canadian hemp. The "recovery," however, lasted but four days, and the edema returned, though the drug was continued.

Deutsche medizinische Wochenschrift, November 11, 1909.

Physiology and Pathology of Magnesium and Calcium.—Meltzer collects and summarizes some of the results of the investigations which he and his coworkers have carried on at the Rockefeller Institute. He says that little is generally known of the inhibitory action of magnesium, and less of the antagonistic action of calcium to this inhibition. In literature calcium is often spoken of as the inhibitive factor in blood serum. Various writers have shown that calcium may act not only as a depressant, but also under certain conditions as an excitant and as an antagonistic to other depressants. The inhibitive action of other substances than calcium has also been shown. Meltzer's work in association with Auer and others began in 1899. He showed that magnesium sulphate injected intracerebrally into rabbits produced sleep which lasted for hours. A similar injection of potassium carbonate caused convulsions. This raised the idea that possibly magnesium was the inhibiting agent in the animal body. His experiments were all on vertebrates, and were divided into 4 groups, in which the injections were made intravenously, directly into various parts of the central nervous system, into the peripheral nerves, and perfusion of nerve-muscle preparations. By intravenous injections were produced paralysis of voluntary movements, loss of all reflexes and anesthesia, while respiration remained good. With lethal doses death followed respiratory paralysis. For intramuscular injections the best results were obtained from solution of molecular concentration, for intravenous, of one-eighth molecular. Doses *per os* produced paralysis only in immense doses and following double nephrectomy. The second group of experiments included intraspinal injections in monkeys and men. Moderate injections caused loss or reduction of sensation and motility below the lumbar region lasting many hours. Larger doses caused unconsciousness without respiratory involvement. Still larger doses caused death by respiratory paralysis, which, however, could be prevented by artificial respiration. The circulation was in no wise injured by this procedure. Introspinal injections of sulphate of magnesium have been made in men many times, especially in cases of tetanus, and frequently repeated. In every case the convulsions were succeeded by muscle relaxation, and often coma. In from 20 to 30 hours all symptoms disappeared without any after effects. All of these and many other experiments demonstrate the inhibitory and depressive action of magnesium salts. The antagonistic action of calcium to this is equally striking. If a rabbit is completely anesthetized by magnesium, and then a calcium chloride solution is injected intravenously, the symptoms disappear at once. The respiration deepens, the reflexes return, and before the injection is finished the animal attempts to move and sits up naturally or hops away. This antagonism of calcium for magnesium was observed in all cases in which the magnesium was given subcutaneously, intramuscularly, or intravenously, but not when it was injected into the medulla, or intraspinally or was applied locally to the nerves. Strontium causes no antagonism to magnesium. Physostigmine in therapeutic doses improves decidedly the respiratory action injured by magnesium without affecting the other actions of the drug. This makes physostigmine a valuable drug in magnesium anesthesia. Magnesium delays the appearance of rigor mortis, whereas calcium hastens it. Of the three elements potassium, calcium, and magnesium, potassium is the least poisonous, and magnesium most so. Variations in this are due to confusing the poisonous action on single organs with those on the body as a whole. Every poisonous substance kills an animal by its action on the organ for which it is most poisnnous. The relative toxicity of the ions of magnesium, calcium, potassium, and sodium for the entire animal is in inverse proportion to the amount of the respective element found in the normal serum.

Intermittent Claudication.—Goldblatt states that this disease, first described as an intermittent lameness, is now known to affect not only the lower limbs but also the upper, and other organs as well, so that one speaks of intermittent claudication of the tongue, the intestines, the spine, etc. He reports four cases of the disease. The condition in many ways resembles migraine, and in some cases, instead of being an arteriosclerotic stenosis, may be a neurosis or spasm. Therapeutically must be considered four methods of recovery: resorption following recovery of the endarteritis, so that the diseased artery is again competent for the blood stream, the formation of new blood-vessels in the surrounding tissue, dilatation of collateral vessels which may carry the blood supply around the obstruction, or the disappearance of the cramp of the vessel. The most rational method of aiding all four of these factors is the production of arterial hyperemia. For this purpose the author recommends light baths and electric foot baths. He has had no experience with Bier's method.

Cerebrospinal Meningitis in the Nursling.—A. Lesage says that cerebrospinal meningitis in the nursing infant may be so ill-defined that a diagnosis is difficult. In general the symptoms are fever, agitation, loss of appetite, refusal of food, diarrhea, and evidences of suffering. All these symptoms might indicate gastroenteritis. The distinctive ones are stiffness of the body and neck, and Kernig's sign. The abnormal forms are a paralytic form in which the head falls about like that of a new-born infant, an attenuated form with few symptoms, but often ending in optic or acoustic atrophy, a tetanic form, a convulsive form, a comatose type, and a type in which intense nervousness is the chief symptom, combined with strabismus and nystagmus. The diagnosis can be made positive only by lumbar puncture, and the withdrawal of turbid fluid containing meningococci.—*Le Bulletin Médical.*

Book Reviews.

The Medical Record Visiting List, or Physicians' Diary for 1910. New revised edition. New York: William Wood & Company.

This well-known visiting list contains the usual lists for the entry of daily visits, for consultation practice, for obstetric engagements, births, record of vaccinations, register of deaths, addresses of patients and nurses, and cash accounts. Furthermore, there is much useful information on various topics, such as signs of death, hints on making a will, artificial respiration, treatment of poisoning and other emergencies, and a dosage table. The volume is compact, neat, and serviceable; it is made of good paper, and is handsomely bound.

The Physician's Visiting List for 1910. Philadelphia: P. Blakiston's Son & Co.

This visiting list is well made up, with a soft, flexible, leather cover, and good quality thin paper, making it particularly convenient to carry in the pocket. Each double page is ruled for a week, and has space for twenty-seven cases. The first few pages include gestation tables, incompatibility rules, antidotes, weights and measures, both apothecaries' and metric, a full dose list, resuscitation methods, and a comparative thermometric table. In the back are pages for memoranda, addresses of patients and nurses, accounts asked for, vaccination and obstetric engagements, record of births and deaths, and cash accounts. The book makes up as an attractive pocket visiting list.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles by Leading Members of the Medical Profession Throughout the World. Edited by W. T. Longcope, M.D., Philadelphia, U. S. A. Volumes I and III, Nineteenth Series. Philadelphia and London: J. B. Lippincott Company, 1909.

These two volumes of the well-known periodical contain numerous original articles on Treatment, Medicine, Surgery, Gynecology, Dermatology, Pathology, and other special fields of medical art and science. In Volume I Lawrence Flick writes on Hospitals for Advanced Cases of Tuberculosis; Campbell Howard gives a complete *resumé* of the literature on Mikulicz' Disease and Allied Conditions and adds several personal cases; Landouzy discusses Typhobacillosis, an entity first recognized and described by the author; Duval and Vinard write on Sporotrichosis; MacCallum discusses Absorption from the Peritoneal Cavity. There are several other articles of interest and a review of the literature for the year 1908, arranged under the headings of Treatment, Medicine, and Surgery. Volume III opens with an article by Francine, commented upon elsewhere in the Medical Record, on the Treatment of Tuberculosis; an interesting paper by Davina Waterson on Mesmer and Perkins's Tractors follows, the latter being an American quack's panacea for all diseases; Baruch gives statistical data in five hundred cases of typhoid fever; S. Solis-Cohen discusses Grave's Disease and allied vasomotor affections; James J. Walsh gives much interesting information on the *rôle* played by women in medicine of the past; Buerger writes on Migrating Thrombophlebitis; Ochsner writes on the Surgery of Exophthalmic Goiter; Pancoast presents a well-illustrated article on the Radiographic Examination of the Gastrointestinal Tract; several other articles in Otology, Neurology, and Pathology close the volume. The two books keep up the usual high standard of this publication.

Medical Sociology. A Series of Observations Touching upon the Sociology of Health and the Relations of Medicine to Society. By James Peter Warbasse, M.D. New York: D. Appleton & Co., 1909.

This volume is characterized by a good, clear, concise style, sound judgment, and a wide acquaintance with men and things both in the profession and outside of it. The title of the book hardly does justice to its contents. Some of these essays appeared in the *New York State Journal of Medicine* when Dr. Warbasse was the editor, and they carry the arrow of editorial soundness, now as they did when we first read them, straight into the very heart of the subject. The purpose of the book is to break down an artificial barrier that has grown up between the doctor and his public, and to tell to each what ought to be known about the other. Thus we have chapters on public policy and the medical profession, the alcohol question, the venereal peril, Christian Science, the family hazard, preventive medicine, the hospital interneship, the small medical society, doctors' sons, medical libraries, etc. There is an abundance both of wit and wisdom throughout the volume, and he must be dull indeed who cannot garner many helpful truths from its perusal.

Surgical Diagnosis. By Alexander Bryan Johnson, Ph.B., M.D., Professor of Clinical Surgery in the Columbia University Medical College; Attending Surgeon to the New York Hospital; Consulting Surgeon to St. Joseph's Hospital, Far Rockaway; Fellow of the American Surgical Association; Member of the New York Surgical Society. Three Volumes. New York and London: D. Appleton & Company, 1909.

This imposing book of three large volumes was written with the intention of treating the subject of Surgical Diagnosis on fairly broad lines. The needs of the general practitioner as well as the surgeon have been considered. Besides methods of operating-table and bedside clinical examinations, the pathology has been considered, and many details not often found in the writings of surgeons, as bacteriological, hematological, and analytical procedures, are thoroughly and accurately described. The book is profusely illustrated with photographs and radiographs taken from the author's own collection, and from those of the New York Hospital, and of many of the author's confreres in New York and Baltimore.

Volume I, of 810 pages, covers the subjects of wounds and their diseases, diseases of the soft parts and of the bones, tumors, fractures and dislocations, syphilis, the *x*-ray, the head and neck, the thorax and breast, the abdomen in general, and the peritoneum and injuries of special abdominal organs.

Volume II, of 777 pages, is devoted to the intraabdominal and genitourinary organs, the kidney alone taking up eleven chapters, and the bladder eight more.

Volume III, also 810 pages in length, discusses the spine, the nerves, the pelvic bones, and the extremities, and contains an appendix covering the recent advances in the knowledge of a variety of subjects, some surgical and others more or less closely related to surgical diagnosis, as the recent discoveries anent the parathyroid glands, the methods for the detection of the *Spirochetæ pallida*, exophthalmic goiter and hyperthyroidism, regional diagnosis of brain lesions, the serum diagnosis of syphilis, and the newer studies of status lymphaticus.

The author sticks closely to his subject of surgical diagnosis. Nothing is said as to treatment or operation, and the domain of the gynecologist is omitted *in toto*. While operative procedures are neglected, diagnostic ones, such as esophagoscopy, cystoscopy, ureteral catheterization, etc., are considered in full. The book is written in simple, straightforward English. As large as many systems of surgery, but the work of one man, it is much more of a unit than most books of its size, and is certainly the most extensive work on surgical diagnosis in English, if not in any language. The illustrations, and especially the radiographs, deserve especial commendation. The large, clear type, the insertion of heavy face type for subheadings, and the complete absence of small type notes make the book easy for reading and reference alike. The improper use of the word tubercular where tuberculous is meant is a minor error which may easily be overlooked in a work of such exceptional merit. The author is surely to be congratulated upon the completion of such immense labor with such happy results, and the surgeon and practitioner are also to be congratulated upon the publication of a book which cannot fail to be of the greatest practical help in the diagnosis of surgical diseases.

An Introduction to Chemical Analysis. For Students of Medicine, Pharmacy, and Dentistry. By Elbert W. Rockwood, M.D., Ph.D., Professor of Chemistry and Toxicology, and Head of the Department of Chemistry in the University of Iowa; Author of "A Laboratory Manual of Physiological Chemistry." Third revised edition, with 20 illustrations. Philadelphia: P. Blakiston's Sons & Co., 1909.

In the present revision of this work the author gives greater prominence than before to the ionic theory of the nature of solutions. This is quite necessary for those who wish to keep pace with the present day developments of chemistry. The book is divided into three parts, dealing respectively with qualitative analysis, volumetric analysis, and applied analysis; this last part containing chapters on the sanitary examination of water, the detection of poisons, and blow-pipe analysis. The work will form a useful companion to any course in chemistry, and as an introduction to chemical analysis it is of more than ordinary value in that it is calculated to make the student think for himself, and it also shows the relation of chemistry to materia medica, physiology, and toxicology.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 4, 1909.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

The Theoretical Considerations of the Wassermann Reaction and Its Practical Application, Based Upon a Study of 2,750 Cases.—Dr. D. M. KAPLAN read this paper. This reaction depended upon two factors: first, the syphilitic serum was said to possess the power of binding or deviating complement when brought in contact with the antigen; secondly, the hemolytic system, consisting of any blood corpuscles plus their hemolytic amboceptor, added subsequently, or rather after the deviation of the complement was more or less complete, gave no hemolysis. From the 2,930 analyses carried out at the Montefiore Home laboratory he believed that a syphilitic infection, after the subsidence of the acute manifestations, and its gradation into secondary and tertiary stages, produced changes in the various organs, preeminently the liver and heart, and that these organs served as depots of the antigen. These organs furnished the true luetic antibody, as well as other bodies of unknown chemical and biological nature. These depots were differently affected by the syphilitic virus, depending upon the patient's constitution. The stronger the individual resistance and the milder the infection, the sooner would the manifestations disappear, and the quicker did the reaction become after appropriate treatment. Mercury in proper dosage did away with the reaction, as well as most of the symptoms. It might be that the antigen depots were affected by the treatment so that no more molecules were furnished to the serum capable of liberating the inhibitory principle from the antigen used, or that the mercury neutralized the various antibodies formed and rendered them inert for complement deviation. It was not erroneous to argue that whereas the syphilitic serum treated with mercury was not capable of doing the same as the normal serum treated with mercury, that in the former the mercury was bound to the bodies responsible for the inhibition, rendering these bodies inert, so far as deviation of complement was concerned, and that in the normal serum, the mercury was not bound and, therefore, capable of uniting with the inhibitory body of the subsequently added serum and rendering it negative. An interesting phenomenon was observed when they worked with sera containing bile products; all such sera gave a positive reaction, although in most of them syphilis could be positively excluded. The majority of the sera submitted for analysis were for diagnostic purposes. The question was asked, "Was the serum from a patient with syphilis or not?" Dr. Kaplan did not believe it was just or safe to render a decision either one way or the other. It must be remembered that in the absence of bile in the serum, excluding various clinical conditions, a positive reaction certainly meant syphilis. It should not be forgotten that certain luetic sera gave a negative reaction; therefore, a negative result for diagnostic purposes was valueless. He advised that sera should be sent to the laboratory for diagnosis only when the clinical findings were extremely obscure. Knowing the shortcomings of the test, the doctor must form his own conclusions, or give the patient the benefit of the doubt, and treat him for lues, unless time was a factor and more urgent interference was necessary. This was specially true in surgical conditions of the brain and spinal cord. He believed that whenever time permitted, when alarming symptoms did not urge an operation, the patient was to be thoroughly mercurialized and the least improvement noted. If no improvement was apparent, plus a previous negative reaction, the underlying cause was likely not syphilis and operative interference was justifiable. Surgical skill was also to be resorted to when the reaction was negative in cases where the syphilitic deposit was accessible with safety, and without injury to neighboring parts, but it was advisable to exhibit mercury first. One should not send sera from a treated patient for diagnosis and not acquaint the serologist with this fact Dr. Kaplan said he believed the system recommended by Noguchi appeared much earlier as an indicator of syphilis than that championed by the Wassermann school. The Noguchi system could also be utilized to a greater advantage therapeutically. Having obtained on a previous occasion a positive reaction with this method, it persisted longer after treatment, sometimes remaining weakly positive weeks after the Wassermann reaction became negative. It also gave a positive reaction with sera from jaundiced individuals. Its simplicity, as well as the mode of keeping the biological reagents, certainly made it a desirable addition to the serologist. From the data given Dr. Kaplan's conclusions were as follows: (1) Not only syphilis but many other conditions gave a positive Wassermann reaction. It was not strictly specific for syphilis. (2) It was also not specific in the sense of Ehrlich. (3) For diagnostic purposes a negative reaction was of no value excepting when the patient showed signs suggestive of an initial lesion or symptoms bordering on this period. (4) Having excluded certain conditions, a decidedly positive reaction by both methods was highly suggestive of syphilis, even if no direct history of the infection was obtainable. (5) It was of no value to perform tests of sera without acquainting the serologist with the therapy. (6) A negative Wassermann reaction was an indicator for the cessation of treatment.

DR. CHARLES L. DANA said that Dr. Kaplan's work had been so carefully done that he had every confidence in the conclusions drawn and the observations made. Dr. Dana had had the test practically applied in about thirty patients during the last eight or nine months; these tests were made in the laboratory by Dr. Hastings, or by those under his direction, and the work had been very carefully done. The cases which were really the most important, from his standpoint, were those that bore upon syphilis of the nervous system. In the first place, regarding the subject of diagnosis, he not infrequently met with cases of rather acutely progressive paraplegia which seemed like cases of syphilitic spinal paralysis, but which might be the spinal type of multiple sclerosis or due to a compressing tuberculous process. Three cases of this kind were subjected to the Wassermann reaction; both the blood and cerebrospinal fluid were tested, with negative results. The tests were repeated and were again negative; there was no lymphocytosis. This led to the conclusion that the cases were multiple sclerosis, as no other symptoms of that disease were present. Dr. Dana thought that when the test was perfected, especially when the cerebrospinal fluid was tested also, the Wassermann reaction would be a decided help in diagnosis. When it came to the question of help in the treatment, so far as the neurologist was concerned, not much had yet been achieved. When a patient, however, had locomotor ataxia and the disease was arrested, the Wassermann reaction, if found, would lead one to keep up active treatment. The persistence or early reappearance of a positive reaction would also be a help in determining that treatment should be kept up.

DR. H. NOGUCHI said that after a clear presentation of the subject by Dr. Kaplan he had very little to add and he congratulated Dr. Kaplan in having entered into such extensive studies with the reaction. As a laboratory man he might, however, add a few hints which might be useful to those who were doing the test. When the test was properly carried out there were very few instances where the so-called non-specific positive reactions occurred. As a

matter of fact those who reported a large percentage of such results were somewhere at fault with the technique, namely, too much of the antigen was usually employed. It was well known that the exces of this reagent could give rise to non-specific reaction with certain diseases, no matter what system was employed. He, therefore, advised those who got such results to reduce the amount of antigen to such quantity as to not give over-sensitive reaction, since the delicacy of the test could be adjusted to any degree one desired to have. It interested him very much to note that the result which Dr. Kaplan obtained in a comparative study of thirteen hundred cases by the original Wassermann and his own method indicated clearly that the latter was more delicate than the former, and was as reliable as the former. This confirmed the findings of himself and of Dr. Howard Fox who made a comparative study of two hundred cases, and the result of Drs. Rosanoff and Wiseman on more than four hundred cases of insanes tested by his system upheld his view of the reliability of his method. It was not necessary to emphasize here that his method was very much simpler. Dr. Noguchi also found it interesting that jaundice gave a positive reaction to the Wassermann but not to his system, a fact which should also be considered by those who were going to adopt either of the methods. Finally, the study on the effect of the bile on the reaction was quite original and interesting. It might probably be due to the action of lipase and of coferments contained in the bile on the lipase substances serving as antigen, because liberation of certain fatty acids might lead to the inactivation of the complement.

Resuscitation by Means of Electric Currents of Subjects in a Condition of Apparent Death.—Dr. Louise G. Robinovitch read this paper and made demonstrations. Artificial heart beats and respirations were caused to take place by means of rhythmic electric excitations with various electric currents. The speaker's method consisted of (1) excluding the head from the circuit; (2) applying the cathode to the back of the chest; (3) using in the beginning the smallest possible voltage that would cause the amplest useful cardiac and respiratory reactions; (4) a gradual increase of voltage, if necessary, in order to maintain useful ample cardiac and respiratory reactions. Too ample or too small reactions might be fatal. The rhythmic excitations should be continued until spontaneous heart beats and respirations set in. In severe cases of apparent death the first spontaneous heart beats and respirations were apt to be slow in reappearing and feeble in nature. If the rhythmic excitations were then immediately suspended, syncope was apt to set in again. In such cases the ample artificial heart beats and respirations should be alternated with the feeble spontaneous heart beats and respirations until life was completely restored. Dogs electrocuted or killed with chloroform were resuscitated with the author's method. The first rhythmic excitations were made with from 15 to 20 volts; this potential was gradually increased to 25, 30, 35, 40, 45, 50, 60, or 70 volts of a direct current interrupted frequently, with or without a regulated period of passage. The milliamperage could not be measured on account of the short duration of closure of the circuit, from ¼, ⅛, to ½ second. The opening of the circuit lasted about one to two seconds, according to the gravity of the syncope. It was dangerous to use too high voltage in the beginning, because the cardiac excitability was thereby quickly exhausted. It was all important to economize this excitability to the utmost degree, because apparent death might continue for a period of some five minutes. The speaker had resuscitated with electric rhythmic excitations a woman in a condition of grave syncope caused by chronic morphinism. She had been accustomed to taking 30 grains of morphine daily during a period of two years, and had been suddenly deprived of the drug. She fell into a condition of syncope while being examined; the Sylvester method and rhythmic tractions of the tongue had been tried for twenty minutes without result. Rhythmic excitations with a special induction coil were applied from 20 to 25 seconds and the patient was revived. The coil was devised for use in resuscitation. The wire of the primary coil was 12/10 mm., that of the secondary 6/10 mm. Both coils and the core were of special dimensions. A coil made of coarser wire was useless; a coil made of finer wire was dangerous. Numerous experiments were made to find the proper diameter of the wire. The preferred current for resuscitation was the direct interrupted from 6,000 to 12,000 per minute, with a period of 1/10. Next in value was the direct interrupted of the same or higher frequency. Next in value was the induction current obtained with the author's coil, giving from 25,000 to 30,000 interruptions per minute. Next in value was a current of similar frequency obtained with the Vreeland oscillator, giving either a pure sine wave current or a direct oscillatory current. Next in value was the simple direct current; and the least desirable was the alternating current. Death was seldom instantaneous in subjects electrocuted accidentally. In the majority of cases there was simply cardiac and respiratory paresis, the patient continuing to breathe for some time after the accident. In spite of the application of all methods known, such patients generally died within one-half hour or so after the accident. Electric rhythmic excitation should be applied before removing the patient to the hospital. Subjects electrocuted at Auburn prison could easily be resuscitated with rhythmic excitations applied after the first shock with high voltage, 16,000 to 18,000 volts, six to nine ampere, because the pulse was perceptible after this shock. In numerous experiments the author never failed to resuscitate electrocuted dogs that showed the slightest sign of blood pressure. It was the shock with the low voltage that killed, because it induced ventricular tremulation. The method of legalized electrocution was unscientific; the voltage used was too high; the application of the electrodes, one at the leg, was contrary to the end in view; the leg was not a vital organ; the leg electrode should be at the back of the chest; with the current thus concentrated, cardiac and respiratory paralysis could be induced with a low voltage. Dr. Robinovitch presented three of her models of apparatus for resuscitation. (1) A wheel interrupter of a direct current used either for anesthesia or resuscitation, for hospital service. (2) A double ribbon interrupter of a direct current for resuscitation, for ambulance service. (3) A special coil with a ribbon interrupter, giving from 20,000 to 30,000 interruptions per minute, for resuscitation in ambulance service.

Electric Anesthesia or Sleep.—If properly applied, all electric currents produced a certain degree of sleep and anesthesia. Dr. Robinovitch found experimentally that all alternating or induction currents were dangerous for central application. The safe currents were the direct and the direct interrupted, with or without a regulation period of the passage of the current. But the safest of these was the direct interrupted, 6,000 to 12,000 per minute, period 1/10. These direct currents were invaluable in the treatment of the insane. The effect of all currents was probably due to their being stored up in the body and to their electrolytic effects. The stored up direct current in the human body could be measured with an ordinary milliampèremeter within one-half hour after the beginning of the passage of the current. The cathode should always be applied at the head. The anode at the head caused dyspnea. If applied centrally, the induction current caused death within one hour, with high temperature. The alternating current was the most deadly of all to cellular life

The d'Arsonval high frequency current had an irregular wave, the effects of which were seen on an animal in the circuit; the animal shivered synchronously with the rapid succession of the irregular wave. Dr. Robinovitch was the first to use electric anesthesia in laboratory work, in 1906, and she was the only one to-day who used this anesthesia instead of chloroform. All electric currents caused abortion in the pregnant animal. The bad results obtained by Dr. Brewer and others in this country were due to the use of dangerous currents and bad interrupters.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 28, 1909.

DR. JOHN OSBORN POLAK IN THE CHAIR.

A Case of Hematoma of the Abdominal Wall Simulating a Dermoid Tumor.—Dr. SOLOMON WIENER reported this case. The patient was a woman, forty-two years old, with no history of tuberculosis, syphilis, or typhoid fever. Six weeks before she was examined she had fallen on her back on a wooden floor. She had a slight pain referred to the lower abdomen, which soon subsided. For three weeks she had experienced occasional dull pain, and for several days had noticed a swelling of the right side of the abdomen. There had been no vomiting, disability, disturbance in urination, nor defecation. She sought advice solely because of the presence of a palpable tumor. Palpation disclosed the presence of a smooth, rounded mass, about the size of the closed fist, extending from just below and to the right of the umbilicus to above Poupart's ligament. It was firm, not elastic nor tender. It was slightly movable from side to side, but not from above downward. The preoperative diagnosis was dermoid tumor. The anterior rectus sheath was incised and the muscle was bluntly divided. In so doing a cavity was entered from which about a pint of old clots and tarry blood was evacuated. The cavity was situated between the rectus and its posterior sheath, with several side pockets branching out into the belly of the rectus. There was a distinct lining membrane, and the muscle fibers forming the wall of the cavity were of a dirty, greenish-gray color, ragged, and felt soft and degenerated. The pathologist's report on the pieces of muscle removed was chronic inflammation. It was comparatively easy to differentiate the tumor from an intraabdominal one. The differential diagnosis was not so simple. Of the causes of tumor formation in this locality, abscess, gumma, tuberculosis, hydatid cyst, lipoma, or actinomycosis hardly came into consideration. They were readily ruled out by the history and the physical signs. There remained only a metastatic growth, dermoid, and hematoma to differentiate between. In view of the excellent condition of the patient and the absence of all other local signs and symptoms, a metastatic growth could fairly be ruled out. The history of the fall upon her back might point very strongly to hematoma. Yet the well known frequency with which patients first notice solid tumors after some slight trauma, the location of the mass, and its physical characteristics, pointed very strongly toward its being one of the latter. The mistaken diagnosis made it seem worth while reporting. There could be but little doubt that when the patient fell supine the rectus muscle was subjected to a sudden violent stretching between its fixed points, with rupture of some of its fibers, and possibly of some branch of the deep epigastric vessels. Treatment should consist of incision and drainage whenever the hematoma was large. Hematoma of the abdominal wall, other than such occurring during convalescence from typhoid fever, and such as were due to direct injury, were exceedingly rare.

Dr. SIDNEY D. JACOBSON said that a dermoid was merely a fibroid tumor, harder in consistency and of a closer texture. It might occur in any part of the body where connective tissue was found, but was most common in fasciæ and in tendons. He reported the following case: A patient, thirty-two years old, married, a multipara, had noticed for several years a slowly growing lump in her right lower quadrant. Lately the skin over this growth became irritated because of the pressure of her corset. Upon examination a round, smooth, hard mass was found. By exclusion a diagnosis was made of a dermoid of the abdominal wall, situated within or intimately connected with the transversalis fascia. The mass could be moved in the long axis of the patient's body, but not transversely. The mass could be moved across the fibers of the muscle or fascia holding it, but not in the direction of those fibers. It was plain that the tumor must be in the transversalis fascia. Enucleation of the mass was a simple procedure and the patient was now well. Upon section the tumor presented a white, glistening surface, and the tissue grated under the knife as it was cut. Upon microscopical examination it exhibited the characteristics of a dermoid tumor, with spindle-shaped cells in small numbers scattered through a dense stroma of parallel fibers very closely knit together.

Dr. H. N. VINEBERG said that he had operated upon two similar cases; in neither of these was there much difficulty in making a diagnosis. One case was a very extensive one, and he experienced some difficulty in bringing together the muscles after the operation. As a rule one must go quite deep into the tissues in the removal of such tumors. He did not recall any case of large hematoma of the rectus muscle resulting from a fall.

Dr. S. WIENER said that the suggestion made that the tumor should have been aspirated in order to aid in making a diagnosis was a good one, but the blood was so thick and tarry that it could have been accomplished only by the use of a very large aspirating needle. Moreover, even if some blood had been so obtained, they would still have considered that they were dealing with a rapidly growing, hemorrhagic, solid neoplasm.

A Case of Hematometra in an Aged Woman.—Dr. ARTHUR STEIN reported the case of a woman, 66 years old, a widow, who had had two children, the last thirty years ago. Two and a half years ago she began to urinate quite frequently, and she had difficulty in starting the stream. At the end of urination there was a burning sensation. She had no thirst, no loss in weight, no bleeding, no leucorrhea, but she did complain of pain in the lumbar region. She had edema of the legs. She noticed that her abdomen was becoming larger. The external genitals were normal. The vagina was senile; the cervix was about one-half an inch long and was pushed backward. No body of the uterus could be felt. In its place, however, was a large, round mass with smooth surface, cystic, and somewhat movable. It occupied the whole of the small pelvis and pressed down the anterior wall of the vagina. The diagnosis made was either a myoma of the body of the uterus or a monolocular ovarian cyst. There was also an external inguinal hernia. A panhysterectomy was performed. In operating the uterus was accidentally punctured and about twenty ounces of chocolate-brown colored blood escaped. The microscopical examination showed nowhere any signs of malignancy in the body of the uterus; in the wall of the cervix, however, instead of finding normal cervical glands, there were columnar cells in many layers, in some places still maintaining the glandular type; in others they had undergone metaplastic changes and were transformed into cells of the squamous type. The diagnosis was made of a large hematometra and adenocarcinoma of the cervix uteri. The patient made an uneventful recovery. In going over the literature of the past thirty-two years he said he was unable to find a similar case.

Dr. EUGENE COLEMAN SAVIDGE reported a similar case.

A woman, sixty-five years old, came to his office apparently presenting an ovarian cyst which she wished removed. In order to learn the position of the uterus, a sound was introduced, and this was immediately followed by a gush of dark, unclotted blood. He washed the uterus out, packed it, and sent her to a neighboring hotel. She made a good recovery. Three years later, when she was sixty-eight years old, she had a similar occurrence; the uterus was emptied again as before. A third time the uterus filled. There was no pathological report. There were no malignant conditions. About six years after first coming under his observation she died of diabetes.

The Care of Pregnancy and Labor Complicated by Nervous Overdevelopment.—Dr. Franklin S. Newell of Boston read this paper. There was a widespread theory in the medical profession as a whole that the duty of the obstetrician was satisfactorily performed if the maternal life was saved. The life of the child was usually considered as a secondary matter, and the after health of the mother received little or no consideration from the average practitioner. No man should feel that he had conducted a case of labor properly in which a child was lost after reaching a viable age, when he had had personal charge of the case throughout pregnancy and labor. Many serious injuries might be inflicted upon the child which might affect seriously its after health. The after health of the mother was a consideration which should receive serious attention, but which was seldom considered until too late. Each patient should be studied carefully, particularly in relation to her power of standing pain and what effects the long-continued pains of labor might have upon her after life. The modern civilized woman was a doubtful risk nervously, although she might be physically well equipped. It was, therefore, an important part of their professional duty to lessen the strain during pregnancy and labor by every means possible. Every patient brought up under the conditions of city life should be considered as abnormal unless she could be proved to be normal by the most searching examination. In each case it was necessary to learn what the patient's previous life had been In many cases it would be found that she had been subjected to such educational and social strain at the time of puberty that she had become merely a bundle of nerves. It had been estimated in Boston that the majority of girls who entered society had at least one or more nervous breakdowns, demanding a modified rest cure, before reaching the age of twenty-five, the time at which a woman should be at the height of her powers. The same might be said of a large proportion of college women. A third group of women were those who had always been sickly and delicate. A class which should receive careful attention were those who had shown no definite weakness before pregnancy, and in whom no definite pathological conditions during pregnancy could be discovered, but who developed a lack of accommodation to pregnancy. They suffered from minor toxemic conditions—vomiting, did not improve physically during pregnancy, did not take proper exercise, and came to labor in poor physical condition. The general indications to be met in the treatment of unfit parturient women might be divided into prophylaxis and palliation. There could be no doubt but that the pernicious influence of early education was one of the most serious factors with which they had to deal. The social standard was so definitely set that a girl's education was crowded into a few years, so that she could be turned out as a finished society product at a definite age, with all the modern accomplishments, and this necessitated a system of hot-house education at a time when the girl was undergoing her greatest physical development. Few parents would be socially so ambitious as deliberately to sacrifice their daughter's welfare if the risks were carefully pointed out and the means of minimizing the damage furnished. Each patient should be studied in order to determine the class to which she belonged. If a patient was considered unfit, the hygiene of her life should be regulated, and she should be treated as though pregnancy and labor were pathological conditions. Many patients could stand operation well, although a long-continued strain would predispose to physical or nervous collapse. In the borderline cases, and in those in which it was calculated that no definite harm would result from labor, much might be done toward lessening the pain and exhaustion by the early use of anesthetics; morphine and scopolamine might be employed in certain cases with advantage. The advantages of surgery should be employed in these cases, and the patients delivered instrumentally at the earliest moment possible without the risk of undue damage. An important part of an obstetrical case was the supervision of the convalescence and the repair of the damage caused by labor. The custom of allowing patients to get up at the end of ten or twelve days was pernicious; three weeks in bed after confinement was none too long to insure a good result. Malpositions and lacerations should be attended to before the patient got up. The physician and not the nurse should have the personal charge of the patient from the beginning of her labor. It was clearly recognized to-day that the elective cesarean section, performed before labor began, carried with it nothing more than the ordinary mortality and morbidity of accident when performed by a competent surgeon, and it might unhesitatingly be recommended to patients who were in the class where the life of the child was of extreme importance. This was distinctly an operation to be performed on those who were considered unfit for the strain of labor, and in whom it was feared that pelvic injury at the time of delivery might produce invalidism.

Dr. Edwin B. Cragin believed that the most important part of the paper related to prophylaxis; the facts were that in cases with this sensitive, high tension nervous system, the women often simply "pressed the button" and then expected the obstetrician to do the rest. The problem was to overcome this faulty development. It must be admittted that the girl was overworked in school during her developmental period, during the first years of her menstrual life. One could see any day such a girl walking along Fifth avenue carrying home a large bundle of books to study late in the evening, when she needed time for rest and development. This certainly did not tend to make her fit for maternity. Dr. Cragin had compared the life of the girl in the city, after leaving the preparatory school, with the life of the girl in college; this comparison resulted in favor of the college life. The alternative was bridge whist, afternoon teas, late hours, etc. If one asked the educators of girls to-day what the chances were for a girl with a college education, as compared with one without it, they would tell at once that the better chances rested with the girl with a college education. They had a great advantage Dr. Cragin viewed the matter from another standpoint the training of the man who was to do the obstetric work under the conditions mentioned by the reader of the paper Years ago obstetrics and gynecology, perhaps also diseases of children, were practised and taught by the same men; later, as gynecology developed, it became separated from obstetrics, as the older men doing obstetric work had usually gone into it from general medical practice, without surgical training, and the younger men, with surgical training, were attracted to gynecology. Now, with the increased demand for surgical skill in obstetrics, the two subjects were coming together again. In watching the men and the staff at the Sloane Maternity he had noticed that, in general, the man who had come from a surgical service made a better obstetrician than the one from a medical service In looking forward, the obstetrician of the future must be the obstetric surgeon, one who had had gynecolog-

ical training and was able to deal with any complications affecting the pelvic organs. Personally, he did not believe that one could tell beforehand whether a young woman with a so-called overdeveloped nervous system was unequal to the strain of labor or not. A great many women, very frail looking, would go through labor without the slightest trouble; whereas, on the other hand, a robust woman, one who rode horseback, who exercised a great deal, with a pelvic floor very rigid, would often have a much more difficult labor. Prior to the first labor none could tell how such a woman was going to pass through it. He agreed, however, that in a certain number of cases, where previous labors had shown that the woman was unable to deliver herself, cesarean section was justifiable. In some cases, if the baby's life was to be saved, this operation was the only alternative. The whole question resolved itself into a careful observation of both the mother and baby; the preparation of the obstetrician to enable him to deal with surgical complications; the realization that the work of the obstetrician required skill in the use of other instruments aside from the obstetric forceps.

Dr. Eugene Coleman Savidge said that there must first be pregnancy in the nervously overdeveloped before it could be managed. If women were overcivilized enough there would be none to manage. If they were properly educated, maternity would begin and end naturally. Improper education caused the troubles under discussion. He believed that woman was entitled to her maximum development, mentally, morally, and physically; that was to say, to her maximum nervous development. The question was What was this maximum, and what were the results of nervous overdevelopment? A woman might be educated out of proportion to her possible destiny, out of sympathy with her environment, and still be within the scope of her mental and physical capacity. Happiness being the basis of health, the question only became medical when it resulted in unhappiness. Woman might be said to be overcivilized when her nervous system disqualified her for utility as sweetheart, wife, or mother. This was the viewpoint of man, the Church, and the State. Individualism was the particular enemy of the State. The right to develop her individuality might seem more sacred to the woman herself than her communal function of breathing the breath of life into masculine clay. The overstrained, broken down athlete was muscularly overcivilized. The intellect of a Guy de Maupassant, pushed by every form of stimulation beyond the limits of finite capacity, was another form of extreme overcivilization. A training that disqualified for the average obligation the average return to the race for the blessing of existence, was an overcivilization. Nature had a very definite average for each species, and had implanted a strong instinct to hold these limits. The unfair division of vital force, the overdevelopment of the psychical element, left the physical, especially the glandular elements, undeveloped or demagnetized; and we had an almost sexless mentality instead of a woman. Nature stopped this process of overbreeding by withholding posterity. The basis of life must always remain the primitive and elemental gland call for cell union. A demagnetized gland, regardless of bulk, lacked the primitive power. We saw men enduring, aspiring, inflicting death, and even losing life for the elemental and primal, but never solely for the brilliant intellectual. Just as the discovery of radioactivity of the supposedly ultimate elements had led to a still further division of matter and had revolutionized modern physics; just as the concept of the vital energy of the cell was surely pointing to the cancer cause, so this problem of the conservation and equal distribution of vital force was looming into the medical problem. Even if women were to choose the individuality instead of the posterity there would still be a grave penalty. An infantile uterus had long been recognized as the result of overexpenditure of vital force in intellectual or emotional outlay. Bulk had little to do with the comprehensive malady of infantile uterus and demagnetized gland, and it had a wider moment than question of race and posterity. Less than five years would sometimes change an infantile uterus in an unmarried girl with amenorrhea into a condition of turgid congestion with profuse menstruation. The pathology was obscure, but there was an analogy between this condition and the gastric engorgement and hemorrhage attending certain stages of cirrhosis of the liver. These patients frequently reached the operating table as a consequence, and there as a final penalty gave up their essential essence of femininity, with a result to longevity which had elsewhere been elaborated. Suppose oversubtle women were only partially so and became mothers. We handled them judiciously and delivered them adroitly. On the other hand, suppose nature was trying to shut up the oversubtle within the offending generation by inflicting uterine and mammary atrophy. Our routine gynecology sometimes thwarted her, and helped pass oversubtlety along to another generation. All this being within our capacity, we yet transcended ourselves when we trained women to become mothers naturally; when we kept the local organs from need of local attack. Foreseeing, forethinking, and foreplanning did this.

Dr. Egbert H. Grandin considered the topic under two heads: (1) The sociological aspect was of vital importance to the integrity of the race, and it was the duty of the physician in so far as in him lay to teach his patients the importance of beginning the training for marriage from childhood up. In short, prophylaxis was the self-evident remedy against the rearing of the type of women so graphically portrayed by Dr. Newell. Poor hygienic surroundings during childhood, education of the brain at the expense of the body, lives of leisure without physical exercise, of necessity these factors resulted in undeveloped nerve centers and in infantile genitalia. The end result was that such women were not suitable for entering into matrimony. Should they do so, the physicians were up against the questions propounded by Dr. Newell in the event of conception ensuing, and the resulting child meant simply a second edition of the neurotic mother. (2) The practical phase of the paper dealt with the management of labor, and Dr. Grandin said he had very decided views which were the result of experience, and he could not altogether endorse certain of Dr. Newell's statements. Thus, reference was made to scopolamine-morphine anesthesia. He objected to this because the use of morphine during labor interfered with the eliminatory organs, and it was above all essential that these should act physiologically, especially since just after labor extra strain was of necessity thrown upon them. Again, the chemistry of scopolamine was rather obscure, and the reports from European clinics proved that it was not free from danger both to the woman and to the fetus. He was satisfied that certain well established measures answered better in the case of the neurotic, underdeveloped woman. Fortunately this type of woman was rarely met with amongst the poorer classes, where the remuneration of the physician, at best very inadequate, did not permit of the careful supervision which women in the well to do class could command. The physician should be the master of the lying-in room. Anxious relatives should be excluded Moral suasion could thus be brought to bear and the nervous tone maintained at a higher average. When the uterine contractions became efficient during the first stage, a large dose of quinine intensified the action of the involuntary muscles. Hyocine often controlled the nervous excitement. Chloral equalized the force of the contractions, the intervals between them becoming longer, as well as the duration. The first stage completed, in the absence

of contraindications, chloroform administered during the muscular, expulsive contractions took the edge off the suffering. On the appearance of maternal or fetal exhaustion, version or forceps, according to indications, entered into consideration. Thus he had guided scores of neurotic women through labor, and this too without ever feeling that in the absence of relative or absolute indications the cesarean section was allowable. Indeed, in reference to this latter point, he could not speak too strongly. The field for this latter operation he was opposed to widening unnecessarily lest, as a result, the mortality rate, now at such low ebb, should be materially raised.

Dr. George L. Brodhead said that he had found it very difficult to estimate just how much a nervously developed woman would do in labor. He did not think that one could tell without a previous history how much assistance would be required for some patients, for it was impossible to tell how much pain the woman could suffer, or how far labor would proceed before intervention became necessary. The tendency among women, especially in the cities, was to spend too much time at bridge whist, suppers, and social functions, with too little fresh air and relaxation. Personally Dr. Brodhead had observed that by limiting the diet mainly to proteins after the sixth month, the child would be of moderate development. There seemed to be an inability or an unwillingness or both on the part of many women to stand the requisite amount of pain for spontaneous delivery. In cases of delayed labor, the use of the Champetier de Ribes bags was of the greatest value

Dr. Franklin S. Newell of Boston believed that the educational period for girls must be extended so that they would be subjected to less strain at the time of puberty and in the years immediately following. To lessen this strain on the individual girls, either the requirements of education must be lessened, or the length of time given to education increased. In regard to the question as to whether a college education did more harm than society life for the average girl, he believed that it was certainly no greater if careful supervision was maintained. It was a difficult question to decide in borderline cases how far they were justified in giving a woman a chance. Experience had shown that many patients would react badly to labor, but would stand the strain of operation well. With regard to limiting the patient's diet so as to reduce the size of the child at birth, he believed it was not so much the question of what the woman ate as it was of how much she ate. If the women could be made to eat just enough food to keep themselves in good physical condition, the supply of nourishment going to the fetus would be lessened and the baby itself smaller.

Philadelphia Neurological Society.

At a stated meeting held November 26 Dr. F. X. Dercum reported "A Case of Juvenile Paresis," occurring in a young man, nineteen years old, whose father had been treated for syphilis for a short time by Dr. Dercum before marriage. The symptoms had begun two years previously The knee-jerks were exaggerated. The pupils were inactive to light, while reacting in accommodation. The mental state was one of well-being, without delusions of grandeur. Dr. David Riesman presented a communication entitled "Febrile Mania of Long Duration Ending in Recovery." He reported the case of a woman suffering a mental shock in each of two pregnancies from the death of a close relative. Following the easy and uncomplicated birth of the second child the woman became manaical, repeating frequently various phrases at different times. The mental derangement was attended with elevation of temperature continuing for six months without obvious underlying disturbance Pelvic infection and other inflammatory disorders were considered and excluded. The leucocyte count was preternaturally low, 1,000 in the cu. mm. Insomnia was a most disturbing feature, and large amounts of hypnotics and sedatives were employed without harmful result. Dr. Alfred Gordon presented "A case of Syringomyelia With Involvement of the Face, Scalp and Larynx." The patient was a woman who presented sensory dissociation with respect to heat and touch, and pain on the left side of the face, head, trunk, and extremities and also of the pharynx and larynx, with some wasting of the thenar and hypothenar eminences and exaggerated knee-jerks. Dr Gordon also demonstrated "A Case of Pseudohypertrophic Dystrophy of Upper and Lower Extremities." The patient was a young colored boy who presented the characteristic enlargement and firmness of the calves, with the peculiar climbing method of arising from the floor, and *alæ scapulæ*. The biceps muscles of the arms were firm in extension, while they appeared soft and flabby in flexion. Dr. Chas. S. Potts presented "A Case of Periodic Paralysis." The patient was a young man employed as a stenographer, who on several occasions found himself entirely helpless without apparent cause, and examination disclosed loss of knee-jerks and of response to faradic stimulation. Dr. S. D. Ingham demonstrated "A Case of Probable Syphilitic Multiple Neuritis." The patient was a man who had been treated for syphilis some twenty years previously and who presented foot drop, steppage gait, at one time pain in the lower extremities, temporary slight bladder symptoms, and inequality of pupils, one of which was irregular. Of course there was some question as to the exact etiology. Dr. E. Lindauer reported "A Case of Tabes Dorsalis Showing a Charcot Joint of the Hip." The patient suffered from pains in the lower extremities, with pupillary changes and abolition of knee-jerks, but without ataxia. X-ray examination disclosed the characteristic destructive changes of tabetic arthropathy. Dr. T. H. Weisenburg read a paper entitled "The Occasional Difficulty in Diagnosis Between Brain-Tumor and Central Paresis."

Is the Placenta a Good Culture Medium for Microbes?—Paul Gueniot used the placenta as a culture medium for various microbes in order to see whether it formed a good soil for their development. He cultivated staphylococcus, streptococcus, bacteria of charbon, *Bacillus pyocyaneus*, colon bacillus, and gonococcus. It was noticeable that the streptococcus grew much less plentifully than the staphylococcus and colon bacillus. The placenta is an excellent culture medium for a number of pathogenic bacteria, but the placental relations do not predispose to streptococcus infection. Clinically, in placental retention the streptococcus is rarely present when the discharge becomes fetid. The colon bacillus and the anaërobes are more frequent. Puerperal infections are generally polymicrobic, although the streptococcus is the principal agent in their production. In putrid placental infection it is found to be ether bacteria that are the causes.—*L'Obstetrique.*

Grippal Aortitis.—Michel Marmorstein says that acute aortitis following influenza is somewhat rare. He recites two cases of this complication of influenza, one of which came to autopsy. In general, it is not the number of germs present that occasions the severity of the attack, but the virulence, the sensibility of the subject, and his means of defense against them. There are cases of aortitis found in young persons that arise without any symptoms that would indicate a chronic process. The symptoms are those of dyspnea, dullness on percussion over the aortic area, and pain or discomfort over the same location. Lesions of the vessel and aorta in the course of influenza cause formation of thrombi, favored by the feebleness of the heart and the slowing of the blood current. Such thrombi occur in various organs. In one of the author's cases a thrombus caused a cerebral encephalitis. The author sums up his observations thus: There is no good reason for denying the existence of acute aortitis in young persons. Such lesions may exist as a result of influenza without any other heart complication Considering the large dilatations of the aorta that are found in young persons, it is probable that they result from some form of infectious disease.—*Revue de Médecine.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of December 4, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	576	173
Diphtheria	343	30
Measles	411	3
Scarlet Fever	382	16
Smallpox	—	—
Varicella	178	—
Typhoid Fever	82	14
Whooping Cough	23	3
Cerebrospinal Meningitis	5	8
Malarial Fever	—	—
Totals	2,000	247

Syphilis of the Stomach.—M. H. Pater finds that more men than women are affected by syphilis of the stomach, and that alcoholic indulgence leads to it. It appears in surgical cases in the third stage, in others the lesion is secondary in general. It may occur in inherited or acquired syphilis. The time between the chancre and the lesion varies from two to forty years. It may be a diffuse infiltration, gummatous new formations, ulcerations, cicatrices, or stenoses. It may occur at any part of the stomach, and vary in degree and dimensions. It may involve the mucous membrane or all the coats. There are not always vascular lesions. Symptoms: rare gastric pain, dyspepsia, crises of vomiting, loss of appetite. There may be simple gastric catarrh, functional disorders, gastralgia, gastroenteralgia, etc. When ulcer occurs it gives the usual symptoms. Tertiary syphilis may exist in one of three forms: gastritis, ulcer, and a cancerous type with or without stenosis. There is no characteristic symptom of any of these conditions that differs from the conditions when arising from other causes, hence the diagnosis is difficult. The only remarkable thing about these conditions when arising from syphilis is the rapidity of cure under mercury and the iodides.—*Gazette des Hôpitaux.*

Vertebral Fibromata.—Le Jumtel says that vertebral fibromata may be either periosteal or retroperiosteal. The latter vary in size; small ones produce few symptoms, and their diagnosis is practically impossible. If the tumor is abdominal and is of considerable size it will give the following symptoms, although they are not marked: asymmetrical abdomen with a marked depression on one side corresponding to a protrusion on the opposite side; absence of pain; on palpation a regular, circumscribed tumor of extreme hardness; little effect on the general condition; slow evolution. These tumors are exceedingly rare in the thoracic region, and, as far as recorded cases go, have given no symptoms at all. In the cervical region they are indolent, pressure causes no pain, unless there is interference with the nerves of the cervical plexus. They remain isolated from the soft parts, and do not surround them as malignant tumors would do. They may interfere with the movements of the neck if they become very large. These tumors are not dangerous, but only inconvenient. In rare cases there is compression of the intestines and even obstruction occurs. The only thing to be feared is the change into a malignant form of tumor.—*Journal de Médecine de Paris.*

Plastic Massage in Dermatoses of the Face.—Raoul Leroy says that massage of the skin of the face, even when by unskilled hands, is of value in lessening dermatoses of the face. Associated with diet it constitutes a powerful and easy method of treatment. Each sitting produces a marked congestion of the skin, with elevation of temperature in the skin, and a sort of succulence and turgescence, causing the papules to be more prominent. This soon passes away and the opposite effects result: there is retraction of the papules and whitening of the skin, with a pleasant feeling. Indications for massage are all conditions in which there is poor circulation. Digestive erythemata, acne, melanoderma, facial obesity, chloasma, and seborrhoeic eczema are among them. Acne is especially benefited by it; the papules become smaller and cease to suppurate. In cicatricial forms the new papules evolute without producing cicatrices. The effect of the massage, which is violent, is reducing, and removes pigmentation. It acts on the tonicity of the skin and restores it to a normal condition.—*Gazette Médicale de Paris.*

A BRIEF HISTORY OF THE TREATMENT OF STAMMERING WITH SOME SUGGESTIONS AS TO MODERN METHODS.*

BY G. HUDSON-MAKUEN, M.D.,

PHILADELPHIA.

PROFESSOR OF DEFECTS OF SPEECH IN THE PHILADELPHIA POLYCLINIC HOSPITAL AND COLLEGE FOR GRADUATES IN MEDICINE; LARYNGOLOGIST TO THE CHESTER HOSPITAL, CHESTER; CONSULTING LARYNGOLOGIST TO THE FREDERICK DOUGLASS MEMORIAL AND ROOSEVELT HOSPITALS, PHILADELPHIA.

My object in writing this paper is twofold, first, to emphasize the well-known fact that quackery reigns supreme in the treatment of stammering, and, second, to point out some of the fallacies and absurdities which are being practiced in connection with this treatment. First of all, let me say that there is generally a grain of truth in the chaff which is being dealt out by charlatans for the sustenance of these unfortunate victims, but the single grain is not at all adequate to their needs, at least in the majority of instances.

It has been estimated that there are upwards of three hundred thousand stammerers in the United States alone. It is quite probable that about one-fourth of the entire number would overcome their defect of their own accord, or at least with the little help that always comes from interested friends, but the remaining three-fourths present a very different problem, in that they must expend a great deal of time and energy upon the work of recovery, and secure in addition the assistance of those having acquired a good working knowledge of the anatomy, physiology, psychology, and pathology of the organs employed in the production of speech.

Stammerers are not alike, except in a few characteristics, and they require, therefore, a certain amount of individual treatment. Our experience with the one-fourth of the entire number, to whom I refer as being easily cured and to whom the grain of truth might prove adequate, can, of course, form no criterion as to a basis for the general treatment of stammering, but nevertheless, because of the great ease with which these exceptional few are managed, inexperienced observers have reached false conclusions and formulated so-called "methods" of treatment which are misleading, fallacious, and even absurd.

For instance, a stammerer is told to nod his head whenever he speaks, and because this procedure happens in his particular case to divert his attention sufficiently long to enable him to speak freely for a time, he thinks he has made a discovery and he immediately evolves a theory and establishes an institute with a secret "method" which consists solely in nodding the head in unison with the natural rhythm of speech.

Another advises beating time with the forefinger and thumb, or with the hand and arm or with the foot, during the process of speaking, and each one of these schemes has been dignified as a "method" which has been dispensed for a consideration, and under bonds of secrecy. Experiences, similar to this, have generally been the starting point of the numerous "methods" which have been promulgated, from time to time, and which have resulted only in confusion to the many really severe stammerers who have been seeking relief.

There is even now a separate and distinct method which characterizes nearly every school and teacher engaged in this work, and these methods in many instances amount to little more than tricks, to beguile the stammerer into freedom of speech, while his mind is preoccupied with something else.

It is well known, of course, that many people stammer under certain conditions largely because they think they will. All their past experiences with speech have combined to confirm them in the thought, and it soon becomes a sort of "fixed idea." It is nothing for which the stammerer should be censured, because it is a perfectly natural consequence, and the idea or notion that he will stammer under certain conditions will remain fixed until it has been supplanted by absolute confidence in his ability to speak freely under all conditions.

That this confidence can be acquired in nearly all cases is my firm belief, but to be absolute the confidence must carry with it the ability. It is not enough for the patient to think that he can do it or even to know that he can do it, but he must know that he knows he can do it. Among the many interesting cases that I might cite, illustrating this point, is that of a young woman from the South referred to me by Prof. Coplin of the Jefferson College. She was fifteen years of age and under my treatment for several months. In due course of time she was discharged as cured, or rather as being able to take care of herself. Her speech was all that could be desired for several months, when she developed an attack of appendicitis. Curiously enough, the surgeon who was called to attend her was himself a stammerer, and during the patient's convalescence she began to stammer again in a very marked manner. When she was able to be about, however, she immediately resurrected the note book which she had made and used during her course of treatment, and proceeded to cure herself again. After it was all over, Dr. Coplin called me on the telephone and told me the story, interesting equally to him and to me. It was quite a year afterward, I think, when she visited my office and a more fluent and graceful speaker I have rarely heard. I have

*Read in the Section on Eye, Ear, Nose, and Throat Diseases, Medical Society of the State of Pennsylvania, Philadelphia session, September 27-30, 1909.

referred to this case because it illustrates, among other things, one important point, and it is this: A stammerer is never thoroughly and permanently cured who has not, like this young woman, so mastered the physiology and psychology of speech, that should it ever become necessary he can recure himself. He must, of course, take heed lest he fall, but should he fall he must be able to pick himself up again.

In reviewing briefly the history of the treatment of stammering, we find that such men as Galen, Celsus, Klencke, Dieffenbach, Detmold, Wolf, and others, supposing that the difficulty existed entirely in the tongue, directed their attention chiefly to this organ, and we have records of mechanical contrivances for holding the tongue in certain positions, and such surgical operations as divisions of the hypoglossal nerve, the lingual frenum and the various extrinsic and intrinsic muscles of the tongue. Dieffenbach went so far as to remove wedge-shaped sections of the tongue, Galen cauterized it, Detmold passed needles through it, Kustner applied embrocations, cauteries, and blisters, and Yearsley and Braid excised the tonsils and uvula. Others suggested holding cork between the teeth, pressing the thumb on the chin, lifting the tongue to the palate, beating time, as I have said, with the head, the thumb and forefinger, the arm and the foot, and numerous other such schemes. The story of Demosthenes, struggling to speak with pebbles in his mouth, is well known, but the probabilities are that the pebbles might better have been left upon the seashore, and that Demosthenes became a great orator not because of the pebbles, but in spite of them.

I do not wish to be understood as characterizing all these practices for the cure of stammering as being fallacious, for many of them may have some value in connection with a well-ordered and scientific treatment. To suppose, however, that the tongue is chiefly at fault and to direct our treatment toward this organ, whether the treatment consists in the application of mechanical contrivances, the knife or what not, is manifestly absurd and should not be thought of for an instant. The trouble is not so much in the tongue, nor in the lips, nor in the palate, nor in the pharynx, as it is in something back of them all. It is not so much in the peripheral as it is in the central mechanisms of speech. And thus it happens curiously enough that there is a grain of truth even in the theory and practice of surgery for the cure of stammering, and it is found in the psychic impression of the operation.

I, myself, often think it fortunate on this account when there are tonsils and an adenoid to be removed, a septal deflection to be corrected, or an elongated uvula to be snipped; but these are operations, of course, which always tend toward the betterment of speech whether or not it is of the stammering sort, and they are operations, too, which are frequently indicated in these cases. I have been especially impressed with the large number of stammerers having intranasal pressure due to septal deflections and spurs.

History records also various educative methods for the treatment of stammering, many of which are theoretically and practically sound. Making use of opposing movements in respiration and vocalization, regulating tongue and lip action, exercising patients on difficult words, making use of rhythmic exercises, and whispering exercises are among the most important, but no one of these methods nor all of them combined can be regarded as a complete system for the cure of this affection.

The scientific treatment of stammering must have in view the actual substitution of normal speech for abnormal speech, and its aim primarily, therefore, should be not the cure of the stammering, but the development of correct speech. The cure of stammering should be regarded as of secondary consideration, although of course it follows as a natural consequence. The stammerer's speech is faulty in every particular. His central as well as his peripheral mechanisms are out of gear and his mental attitude toward speech is wholly wrong. The instrument is out of tune, and the player is unskilled in its use. He cannot retune his instrument and if he could he would be unable to play upon it. The affection, therefore, is a complicated one, involving not only all the various mechanisms of speech but also some of the higher intellectual and emotional centers of the brain. Indeed it involves the whole being, and its scientific treatment, therefore, must have for its purpose a thorough reeducation of the individual; it must supplant his stammering speech with normal speech; it must make it easier for him to speak freely than to speak hesitatingly; it not only must correct the stammering habit, but it must remove the fear of stammering, upon which much of the trouble depends.

If we correct the habit, without, at the same time, restoring the patient's confidence in himself and in his ability to speak freely, the cure will be only temporary, and if we develop confidence in the patient, by the use of the so-called suggestive method, whether it be given in the hypnotic or waking state, without, at the same time, correcting the physical habits, as is frequently done, the results are only temporary and of course unsatisfactory.

It is not unusual to hear of stammering being cured in a few treatments or in a few weeks, but it is quite unusual to hear of such rapid cures being permanent. It is possible in nearly every case, by a short-cut suggestive method, to appear to cure stammering, and hence it is that the commercially inclined "stutter-doctor" is able to guarantee a cure and even to promise to refund the money in case of failure. A written guarantee of this sort is nearly always given in these institutes but no one has ever yet heard of the money being refunded, although it is a fact that only a few of the patients are actually and permanently cured. On the other hand, many of them are often made distinctly worse by their unfortunate experience.

The stammerer must be taught to speak in somewhat the same way as a person is taught to play upon the violin or the piano. The stammerer's instrument, of course, must be put in good condition by the removal of all obstructions to good speech, and then, as in the case of the would-be violinist or pianist, he must be taught to play upon this instrument. The exercises, which are purely educational and physiological, must continue for a sufficient length of time to enable the patient to form entirely new habits of speech, and they must, of course, be adapted to the special requirements of each individual case.

Stammering in the majority of instances, therefore, cannot be cured in a few weeks. On the contrary it often requires several months or even years to bring about the desired results. The man who guarantees to cure stammering in six weeks, or indeed who guarantees to cure it at all, is either ig-

norant of the true nature of the affection or possessed of some ulterior motive, and is therefore not to be trusted.

1627 Walnut Street.

THE TECHNIQUE OF AMPUTATIONS WITH ESPECIAL REFERENCE TO OSTEOPLASTIC METHODS.*

By ALEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK.

VISITING SURGEON HAR MORIAH HOSPITAL; ADJUNCT ATTENDING SURGEON MOUNT SINAI HOSPITAL.

The question of technique of amputations is a broad one, and affords possibilities for discussion from many viewpoints. I shall confine myself this evening, however, to the discussion of certain phases of the subject of wide scope, which have afforded fields of fruitful activity in connection with the subject of amputations, especially in recent years. I refer to the formation of a good stump. Indeed, it is practically the only phase of the subject of amputation technique that can be said, so as to speak, to be still alive. With due submission, I venture the opinion that surgeons have not applied themselves to this subject in proportion to the importance which it deserves; and the reason is very manifest; the construction of a good stump is not a life-saving measure. The pleasurable fact that the patient has recovered outweighs, in the eyes of most surgeons, all considerations as to whether the stump is of the greatest comfort or utility to the patient. I hold, however, that in these days when the safety of an amputation has reached such comparatively satisfactory limits, the success of an amputation should not be entirely measured by this criterion. We have arrived at the point where we are willing to spend extra time to ensure the strongest possible abdominal wall after laparotomies, and I see no reason why the same consideration should not be shown toward the formation of a good stump.

It must be admitted, however, that it is not because of a lack of ingenuity that this condition of affairs exists. The various methods that have been devised for the purpose of attaining the best possible stumps are legion, and some of these are among the most time-honored operations in surgery. I believe, however, that the majority of these operations have been devised under a misconception of the essential principles involved in the construction of serviceable stumps. For years I have been practising these operations with an ever increasing sense of dissatisfaction. When Bier in 1807 evolved his method of osteoplastic amputation, I adopted it in subsequent operations, wherever possible, with the result that I have become an unreserved disciple of the principles involved therein. The result has been that practically all of my previous notions on the proper methods of amputating have been dissipated, leaving me with a series of firm convictions on the subject, that I shall now endeavor to place before you for discussion.

In the first place, what do we mean by a good stump? Before a stump can be classified into this category, it must have the following requisites: 1. It must be painless. 2. It must be capable of performing physiological functions, so that the wearing of a prothesis may be possible. Now, if we examine the anatomy of a stump, there are only five structures, or groups of structures, that require technical manipulation, and it is in the disposal of these that we must seek the cause of success or failure. These are (1) skin and cicatrix, (2) muscles, fasciæ, tendons, etc., (3) blood-vessels, (4) nerves and (5) the bone and periosteum.

I shall discuss each of these structures in order.

1. The skin and cicatrix. The proper disposition of the cicatrix, so that it shall not lie directly over the end of the stump, is still regarded as of paramount importance in amputations, and numerous incisions, particularly of the flap varieties, have been devised with this object in view.

In order to prove or disprove this point to my satisfaction, I have examined in the course of many years a large number of stumps, of many varieties of construction. I found, not only that the tenderness of the stump has no relation to the site of the cicatrix whatever, but, furthermore, that the cicatrix was in a majority of cases even anesthetic.

This was strikingly brought home to me in one instance. It occurred in a patient whom I had the honor to present before this section. I performed an osteoplastic amputation in the middle of the leg, in a young man, for Raynaud's disease. I performed the amputation lower down than usual, against my convictions, but in deference to the earnest entreaties of the patient. The expected happened: both cutaneous flaps necrosed, exposing the bone flap in its entirety. Slowly, however, the periosteum of the bone became covered by skin epithelium, and the wound healed. Despite the inauspicious character of the cicatrix the stump is absolutely painless and is capable of end bearing qualities. I am of the firm conviction, therefore, that the importance of the cicatrix in amputations is merely a venerable tradition and should be abandoned. Of course, I do not refer to those rare instances where a sensory nerve happens to have been included in the cicatrix. These are merely exceptions which do not prove the rule.

There is another time honored tenet, that I shall dispose of briefly. It is this: that wherever possible the stump should be covered with skin, that is normally subject to pressure. This notion was derived from the unvarying success observed after Pirogoff and Gritti amputations. As I shall subsequently show, however, this deduction was based upon a false premise. In fact, I discard the question of the quality of the skin entirely, and if pressed by circumstances do not hesitate to so calculate my incision, as to take the skin from anywhere in the neighborhood. My only considerations are viability and absence of infection.

2. Muscles, fasciæ, and tendons. The fact that a stump must be covered by a well padded mass of muscle has long been one of the cardinal rules in performing amputations, and has given rise to many operations, chiefly of the transfixion, inverted cone, and funnel shaped varieties. It is true that the stumps formed by such amputations are objectively very beautiful; they are massive looking, well rounded, and cushion like. Unfortunately on examination the stumps will be found to be quite as tender as those that are covered by practically nothing but skin. Moreover, the advocates of this procedure forget that ultimately the muscles atrophy and leave the end of the stump in as proverbial nude a state as if no attempt had been made to cover the end of the bone.

*Read at a meeting of the Surgical Section of the New York Academy of Medicine, November 5, 1909.

Recognizing the fact that the sawn surface of the bone is the tender point, some surgeons, and Wilms in particular, have attempted to obviate this possibility by covering the end of the bone with fascial structures, or, better still, by tendon. My personal experience is limited to one case, and as far as pain

Fig 1

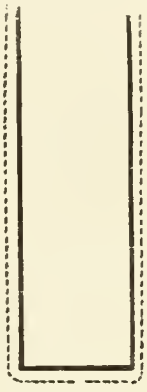

Fig 2

or tenderness is concerned this resulted in an absolute failure. Wilms himself could not obtain an end bearing stump, although he claimed that the stumps were not painful. Inasmuch as no conclusive statistics are available this question can be said to be still in abeyance.

3. Blood-vessels. These not be considered seriously as factors in the production of pain.

4. Nerves. That the cause of a painful stump may lie in the nerves is a fact known to you all and I shall not discuss this phase of the subject at any length. It will be sufficient to say, merely, that only a small minority of painful stumps is due to this cause, and in the vast majority of these there has occurred a violation in the technique of proper nerve division; methods which are known to you all.

5. Bone and Periosteum. Having excluded the four previous structures as factors in the production of painful stumps, we are, *à priori*, forced to the conclusion that the essential etiology must lie in the bone and periosteum. These structures being so intimately related, I shall discuss them together.

The evolution of the disposal of these structures in amputations is highly instructive and interesting to follow. In the simplest method, and, indeed, it is among the earliest, the bone and periosteum are divided at equal levels (Fig. 1). It did not take long for surgeons to discover that painful stumps invariably followed. Conceiving that the pain was due to the bareness of the bone surgeons devised the so-called subperiosteal method, in which a cuff of periosteum was used to cover the bone surface (Fig. 2). But the resuts were anything but good, and, to my mind, even worse. The cuff of periosteum either failed to produce the requisite amount of bone or produced it in such profusion that in the course of time veritable stalactites were formed, and it requires no stretch of the imagination to see how these can contribute to a patient's misery.

The next step was one in the backward direction. Surgeons argued that if an excess of periosteum was baneful, perhaps it would be wise to eliminate the periosteum altogether. As a result the so-called aperiosteal method was devised, in which the periosteum and osteomyelon as well were cut away for a short distance above the sawn surface of the bone (Fig. 3). I have employed this method a number of times in recent years, whenever for valid reasons the osteoplastic method was unavailable, and with, I confess, a fair sense of satisfaction. In one case, however, perhaps due to injudicious selection, necrosis occurred.

Let us now critically examine the reason why the plantar surface of the foot, designed by nature for walking, is not painful, while on the other hand an amputation stump constructed according to any of the previous methods is always more or less so. This may appear to you foolishly obvious, but it remained for Bier to apply the answer lying behind this question toward solving the problem of painless stumps. The answer is this: that in the planta pedis pressure is applied upon normal bone covered by normal periosteum; in the amputation stump, on the other hand, pressure is exerted either upon a sawn surface of bone, or bone not covered by periosteum, or bone covered by inflamed and proliferating periosteum. Acting upon this principle, therefore, Bier devised the method of covering the end of the bone with normal bone, covered by normal periosteum. This is the so-called osteoplastic amputation (Fig. 4). We can now understand the reasons why the Pirogoff, Stokes-Gritti, Sabanajeff, Abrashanoff, and Biers diaphyseal methods of amputation resulted in painless stumps.

Having eliminated pain as a necessary consequence of osteoplastic amputations, it remains to judge the results of such amputations by the second criterion of a good stump, namely perfect physiological function. In the lower extremity physiological function comprises two essentials, support and locomotion. For stumps these same requirements hold good for prosthetic purposes. I do not wish to enter here too largely into the subject of the prosthetic art. I shall merely give you the barest outlines of the principles of prosthetic construction. It is obvious that the best support will be obtained if the weight is borne directly upon the end of the stump. Furthermore, the better the sup-

Fig 3

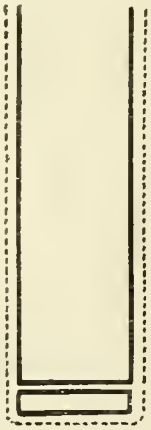

Fig 4

port, the better the locomotion. The attainment of these objects is, however, practically impossible in stumps, not constructed by osteoplastic methods, because of the tenderness. The consequence is that artificial limbs are made so as to draw support from some bony prominence above the end of the stump.

In regard to stumps of the upper extremity, the question of physiological function is not so important; even here, however, perference should be given to osteoplastic technique, because it at least ensures absence of pain and tenderness. I cannot

allow this occasion to pass, however, without mentioning the apparently well directed and meritorious efforts of Vanzetti to enhance the physiological function of stumps of the upper extremity. His ingenious procedure consists in the formation of projecting loops of tendons which are covered by skin. These loops can be attached to various forms of prosthetic apparatus and are capable of performing comparatively complicated movements. The method appears promising and requires more extensive trial.

I shall now return to another phase of the subject of amputation technique that bears strongly upon many of the points that I have already raised. I refer to the solution of the question as to the proper site for amputation. This question is so large that it could easily be made the subject of a separate thesis of considerable dimensions. For this reason I shall discuss the subject merely in a broad way.

The cardinal rule in the solution of the question as to the proper site for amputating is this: Amputate at the lowest possible level commensurate with the existing or prospective viability of the tissues. As I have already said, the quality of the skin or the disposition of the cicatrix should not be considered. The term "seat of election" is a much discussed, and, I fear, a much abused term. This term was much in vogue in former years, when peglegs were the commonest and most available forms of prosthetic apparatus. By "seat of election" surgeons refer to amputations at that part of the leg, usually the upper third, which would enable the patient to wear a pegleg with the best cosmetic effect. I believe, however, that no surgeon should deprive a patient of the possibility of his wearing the best possible artificial leg by any such consideration. The phrase, seat of election, in this sense, can therefore be relegated safely into the limbo of antiquities and should mean nothing but the lowest possible site for amputations. The selection of the proper site depends naturally largely upon the disease calling for the amputation. In a broad way I should urge the utmost conservatism in noninfected traumatic cases and radicalism in rapidly progressive infections and in malignant tumors. There is one malady which I shall discuss more fully; first, because of the frequency of this malady, especially at Mount Sinai Hospital, and, secondly, because the selection of the best site for amputation has hitherto been an extremely delicate task. I refer to Raynaud's disease, or better, as Dr. Leo Buerger has termed it, on the basis of his painstaking researches, thromboangeitis obliterans. Formerly the problem of where to amputate in this disease resolved itself largely into a matter of guesswork. Thanks to a namesake of mine, Moskoviez of Vienna, a test has been offered to us, which affords us a fairly approximate working guide. I describe it briefly. A Martin elastic bandage is applied high up on the extremity sufficiently tight to cause an anemia. After allowing the bandage to stay in place for a few minutes it is unrolled. The extremity is then carefully inspected in order to note the lowest border of the area of primary reactive hyperemia. This is the line where the amputation is to be done. I have found this test to be an extremely reliable guide. When I acted according to this test I have never obtained necrosis; when for some reason or other I saw fit to disregard this test I always obtained necrosis.

In conclusion let me ask you to look up your hospital records of amputations you have performed. I trust and I believe you will probably find that the histories of the vast majority of the patients close with the pleasurable word "cured." This word, however, implies a degree of perfection which the subsequent course of events, if looked into, will not justify. I believe, however, that this consummation will be more nearly approximated, if more frequent resort is taken to osteoplastic amputations. If I have been able to awaken among you a more extended trial of this method, I shall feel myself amply repaid.

925 Madison Ave.

THE PHYSICAL DECAY OF NORTHERN EUROPEANS IN OUR NORTHWEST.

By CHAS. E. WOODRUFF, M.D.,

MANILA, P. I.

In an editorial article in the Medical Record of June 22, 1907, mention was made of the recently discovered harmful effects of the excessive sunshine of Western Canada, and the fact was pointed out that an important experiment in migration was now being unconsciously worked out by the people flocking into that wonderfully rich country. The query as to their ultimate survival has been answered much sooner than was anticipated, for Dr. S. Carlsen of Spring Grove, Minn., has published in a Norwegian medical journal (*Tidsskrit for den Norske Lægeforening*, No. 10, 1909) an account of the rapid decay of Norwegians in our own Northwest, the title of the article being "Influence of climate upon North European emigrants, particularly Norwegians in America." He mentions an article by Dr. Austin O'Malley (*American Medicine*, November, 1908), whose investigation of 34 Irish families, who migrated to the latitude of Maryland after the famine of 1847, and who have since decayed in a startling manner from insanity, epilepsy, chronic nephritis, tuberculosis, and neurasthenia, besides producing a woful number of chronic drunkards. The families which settled in Canada did far better. Carlsen then goes on to show that a similar fate has overtaken the Norwegians who, about the same time and since, have settled in our Northwest. In certain Chicago districts they have been almost completely replaced by southern Europeans; and the decay of those in the rural districts of Minnesota and the Dakotas is marked "in spite of good hygienic conditions, good food, large, airy, and warm houses, and temperate life." The deterioration of the offspring is shown by anemia, lack of development, early dental caries, and catarrhs, while 80 per cent. or more are nervous. "The farmer's daughters are often as slender and delicate as the city women; if we do see a sound, healthy woman with rosy cheeks and strong physique, we may be sure that she is a newcomer from a country district at home." In view of the sturdy condition of the ancestors who built up a prosperous profitable farming community, the decay is amazingly rapid, yet Carlsen states that the Norwegians who settled in Texas about the same time have completely disappeared, not by amalgamation, but by inability of the offspring to develop properly in an unfit climate.

Similar conditions have been mentioned among the Swedes in the Northwest, and he states that Scandinavians are furnishing a deplorable number of inmates of the jails and asylums. Perhaps we

can now see why there is so little trace of the Swedish colonies which flourished in the 17th century in the lower Delaware valley, and though, to be sure, some of the people married into other nationalities and are now represented by mixed type descendants, yet the Nordic type has already disappeared, all the same, through the greater mortality of the descendants with yellow hair and light blue eyes.

In marked contrast to the Norwegian Americans are the phlegmatic stay-at-home cousins so graphically described by Dr. C. K. Austin in the *Boston Medical and Surgical Journal*, July 8, 1909. Norway is a haven for neurasthenics.

Carlsen has come to the conclusion that the blond Norwegians have developed a physique which fits them for the cool, dark, moist climate of the Scandinavian fjords, and that they are injured by both the excessive winter cold and summer heat of our Northwest and particularly by the excessive sunshine against which they have insufficient pigment protection. He shows that they have always died out when they went so far south as Central Italy or Southern Pennsylvania, and that they cannot colonize except in a country resembling their native land. He shows that they can and do survive in Scotland with its 259 cloudy days, but not in Yuma, Arizona, with its 19 or El Paso, Texas, with its 28. Moreover, the excessive number of cloudy days at home has given rise to their instinctive love of the stimulation of their few sunny days, but he states that on coming to America where they get too many such days, they should give up their traditions, hide from the sun, use sunshades, plant shade trees, and avoid overstimulation. He even states that this nervousness is responsible for the appalling number of murders in America—relatively nine times as many as in England and Wales—and enormously greater than in Norway, by the way.

Carlsen's article has made a profound impression in Norway and among Norwegian Americans, and will no doubt check the ancient custom of leaving Norway for southern homes in which permanent survival is impossible. There is already a tendency to look upon all southern lands as places to secure wealth and then return home to enjoy it, and the northern European governments will naturally favor such a policy of repatriation. The ultimate political effects of these new studies of climate and race are therefore bound to be far reaching and revolutionary.

But as for the Canadian West, the ultimate result upon the Baltic type of man must be the same as in Minnesota, only quicker. The hardy blond pioneer himself will survive to old age perhaps, but his children will be smaller, weaker, and more nervous and his grandchildren positively degenerate. The type which should survive there is the swarthy brunet who has been evolved by similar climates in Eastern Europe and Northern Asia.

Among the Norwegians we find the highest percentage of what is now being gradually accepted as the original Aryan, which has had such a profound influence all over the world, whose languages and civilizations are becoming universal. They are the most valuable element of our population, and we should try to preserve them as many generations as possible, unless we are to depend upon a constant stream of immigrants who in time will only look upon America as an outlying plantation, and consider Scandinavia or Scotland as their real home. The medical profession, therefore, has a keen interest in the problem of living in the intense sunshine of Western America.

The decay of northern types shows that survival of migrants is not solely a matter of avoiding the infections, as believed by Colonel Gorgas. His wonderful work at Panama has led him to believe that since Europeans have been able to escape death a few years, therefore they can raise children there, and permanently colonize the tropics, and that the differences between Norwegians and Mediterraneans, so carefully evolved by nature, are meaningless. But really, nature is not foolish to go to all this trouble of selecting the fittest. If Scandinavian colonization is impossible in our west, how utterly impossible must it be in the tropics.

It must not be forgotten that family survival is often possible even when certain types die out. Davenport is proving that Mendel's law applies to man, more or less rigidly. If, therefore, a Baltic type marries a Mediterranean, for instance, the offspring are not blended, but the characters of each parent exist segregated, some evident and others hidden or partly hidden. In subsequent generations the characters may appear as now so clearly explained. We constantly see brothers and sisters of opposite type, and if one type has a higher mortality, the other perpetuates the family and the unfit ancestor leaves no trace.

A recent observation of the offspring of half-breed Indians in Western Canada has shown some to be almost pure Indian in type and some to be almost pure European in the same family. Under such circumstances the lines, by survival of the fittest, revert to the Indian. It is now believed that the ancient Aryan type died out in India quite promptly, although the ruling families may have survived a long time, indistinguishable from Hindus. This is the process which is making our old stock brunet, although in the extreme northeast some few yellow-haired types still persist even where not attributable to infusion of new blood. Havelock Ellis has shown that the same increasing brunetness is an almost universal phenomenon in the great families of England, where, as a rule, the fortunes of the family were established by a blond of the recent invaders, who married into the more brunet native stock, and the blondest offspring disappeared through higher morbidity due to the same defective development shown in higher degree by the Norwegians in America. The kings of England, up to the time of Elizabeth, were generally of this tall blond invading stock, often with yellow hair, as in Edward IV, but the type has almost disappeared in the royal family.

There is no doubt that as we go from the Equator to Scandinavia and Northern Scotland, the average weight of the brain and average intelligence increase. There is also no doubt that we think with our brains and that the bigger they are the better the thoughts. That is the reason nearly all of the world's great thoughts arise in the northwestern corner of Europe or originate with migrants from that place. To be sure, when we find post-mortem that some highly trained specialist attained distinction in a very limited sphere with a brain smaller than the average, some man arises to remark that brain weight has no relation to intelligence. Only recently a college professor expressed amazement that the brain of some other professor was smaller than that of an ignoramus who had never had any training, assuming that college professors were

necessarily more intelligent than those in outer darkness. As a matter of fact some of our grandest teachers have attained greatness simply because they had brains capable of specialization, and have been notoriously ignorant and stupid in other lines.

Brain weight does count after all is said, and it should be our national policy to favor the immigration and survival of races having the highest average brain weight, and those are the races in the blond area of Europe. It is appalling that they should die out as quickly as Carlsen shows and as others have shown. Something can be done to preserve them longer and that something is the realization by the medical profession that nature is not a fool. We must learn why Norwegians can survive millenniums in Norway or its vicinity but not in America, except here and there. Whenever I see a marked blond I always investigate his ancestry and his family is generally found to be a recent arrival, the few exceptions being in those who have remained in our cloudiest coldest places east of the Mississippi Valley. I have gone into this matter more fully in my book, "Expansion of Races" (The Rebman Co.), but this little article of Carlsen's shows that the matter of deterioration of migrants in unfit climates has much more profound results than any of us have hitherto realized. A recent observation of the graduating class of a New England college, where nearly every member was of the intelligent prosperous classes, mostly old stock, showed a remarkable uniformity of complexion—the hair color being medium or light brown. Black hair and dark eyes were decidedly fewer than blond hair and light blue eyes. The class represented the survivors of Aryan invaders of America.

It must also be remembered that northeast and east of Scandinavia we have conditions similar to the east of our Rockies—cold winters, hot summers and excessive sunshine—but that west of the Scandinavian mountains the conditions are almost identical with western and southern Alaska, a place which is already proving wonderfully suited to northern Europeans, for it has the same latitude and same seasons and cloudy climate. There is where survival of the Aryan type can be predicted *a priori* and where experience already proves we are bound to have an influential, rich, vigorous, and highly intelligent population. Since the world has long been in control of this northern type of man, which has also been in Scotland for some two or three thousand years, it is not at all a stretch of the imagination to look to Alaska as the future breeding ground for the supporters of American civilization. The ignorance of Alaska's agricultural and residential possibilities has heretofore prevented our realization of these stupendous facts, but, perhaps, the publicity given to them by the Seattle Exposition will force them on public attention. Perhaps, in time, immigrants from Norway will go straight to the Alaskan fjords, where they will find a new home identical with the old—a new Arya.

To-day I was consulted by an American who had been here less than two months, working daily in the tropical sun. He evidently brought tubercle bacilli with him, but the heat and light have destroyed his resistance and he is now a far advanced case, liable to die before this letter reaches its destination—so rapid is the disease when we are out of adjustment to the climate. If he had gone to southern Alaska he might now have been on the road to recovery.

As a health resort for neurathenics alone, our northwest coast deserves attention from the medical profession, but as a breeding ground for our future governing class, it must be considered seriously by everyone. The Alpine and Mediterranean types now flooding the land and surviving as the fittest in a climate suitable for them, never have upheld an Aryan civilization and never will. For thousands of years they have been organized by a northern blond aristocracy whom they would not permit to engage in trade or the mechanical arts of the people organized. History repeats itself when the conditions are the same, and we are bound to find this northern type of our mixed population, the leaders and the supporters of civilization; and all this in spite of the fact that the two brunet races furnish occasional variations of wonderful ability. Already, many observers have noted the fact that practically all our leaders have names indicating an origin in northwest Europe.

In addition, it is evident why there is such a tremendous movement to return to the ancestral northern home. They find comfort, peace, and happiness in the cool mists and fogs, protected from the goading heat and light of America. Why not shunt them off to our northwest coast? The Carnegie type of American is carrying back "home" immense quantities of America's wealth; can the flow be checked, or is it merely natural law? Chinese, Japanese, Italians, Swedes, Poles, Slovaks—indeed all of them—are beginning to do the same. Is America to be merely the wealth producer for Europe?

THE TREATMENT OF PULMONARY TUBERCULOSIS BASED ON THE ASSUMPTION THAT THE DIETETIC CAUSE OF THE DISEASE IS LIME STARVATION.

DISCUSSION OF THE HYPOTHESES.*

By JOHN F. RUSSELL, M.D.,

NEW YORK.

The mysteries of physiological chemistry are so profound that an attempt to explain pathological chemistry and physiology is but a step into greater darkness. But, since all experiments in the treatment of disease must start from some working basis and the really important matter is the result of such experiments, the excuse for the following is that, right or wrong, the reasoning seems to the writer to have led to a decided improvement in the dietetic treatment of pulmonary tuberculosis and its further application may lead to better results in the treatment of other disease conditions which readily suggest themselves, but which the limit of this paper forbids special discussion of here. For example, it is hoped that it will be made evident that a milk diet without acid, or accompanied by acid foods, is wrong in the prolonged fevers of adults, because it seems well settled that fever is the commonest cause in checking the secretion of hydrochloric acid in the stomach. In consequence lime starvation, more or less severe as the case may be, results. If milk is given raw and undiluted its normal acid appears to be sufficient to activate rennet-zymogen in children, in the majority of cases, but not so often in adults. The latter appear to need a greater degree of acidity. A milk diet accompanied by acid, in fever, is theoretically per-

*See article on the preliminary report of the results of treatment in the MEDICAL RECORD, November 27, 1909.

fect because, in a given quantity, milk contains the greatest amount of lime salts of any food, and casein is the most easily digested of all the albumins. In this connection the old practice of giving "refrigerant" drinks during fever is interesting. All cases of pregnancy and lactation should be treated after this plan. Again, in recent years a great deal of interest has been aroused in the possible relation of epilepsy, tetany, and the nervous manifestations of rickets to disturbances in lime metabolism.[1] Any means which will aid the assimilation of this element should be of value in these investigations. Its bearing upon the work of the surgeon scarcely needs mention. Because the success of his work is so immediatelly connected with the repair of flesh wounds and fractured bones, the normal absorption of lime becomes of the greatest importance. This applies to the management of diet before as well as after operation as will be made clearer later on in the paper.

Such brevity in the following is much regretted but, under the circumstances, unavoidable.

In order to support the assumption that lime starvation is the dietetic cause of tuberculosis it is necessary to show, First, That this condition is equally prevalent and that it is common to all ages. Secondly, How this condition favors the growth of tubercle bacilli. Thirdly, How lime starvation is produced.

1. The most prevalent disease of childhood is rickets. True rickets has been produced in animals by feeding them food deficient in lime.[2] Most writers admit that a deficient supply of lime will result in rickets, but deny that this is the only cause of rickets, chiefly on the ground that the disease develops in children whose food contains an ample supply of lime. It was then pointed out that the result will be the same whether there is deficient supply or deficient absorption of lime and that, in the cases just mentioned, the fault lay with absorption. To answer this it was shown by experiments that lime is absorbed when administered to rachitic children.[3] The suggestion advanced in this paper is that while lime phosphate (and probably other salts of lime) may be absorbed from the alimentary canal and reach the blood current as an inorganic salt, unless it has first formed certain combinations with organic matter it cannot be employed by the tissues as building material. As will be shown later these combinations are the result of the action of rennet. Cases of rickets which develop in children whose food contains a sufficiency of lime are due therefore, to lack of rennet in the gastric secretion.

Rickets is here considered as typical of lime starvation in the young. What are the symptoms of lime starvation in the adult? Rickets should not be regarded as a bone disease merely, for it involves the structure and function of muscles, ligaments, mucous membranes and all the organs of the body, particularly those of the nervous system. In experiments upon animals it has been observed that the symptoms which followed the administration of food lacking in lime varied in the order of their appearance and in their severity. These variations were found to be due to the age of the animal and the rapidity of its growth. Young, rapid-growing animals develop severe bone symptoms first while in the more mature or fully grown, muscular and nervous symptoms predominate. Man is a slow-growing animal and it is a common observation that many cases of rickets pass unrecognized. That is, a child may develop symptoms of muscular, nervous and digestive disorder, which are really due to rickets, but because bone symptoms are not pronounced (the grade of lime starvation being mild) the disease is not recognized until later in life when distinctive bony deformities have made their appearance. In other words, a positive diagnosis of rickets is not made without bone symptoms.

The prominence of bone symptoms in rickets is due to several causes. First, The incomplete development of bone at the age when the disease occurs, consequently failure of their chief function, support. Secondly, The irritation produced by muscular effort upon bones which are not only incompletely developed, but, just at this age, are growing with great rapidity. Thirdly, Their impaired rigidity, due to lack of lime phosphate, resulting in deformity. All organs, including bone, continue to grow during the course of rickets. That is, there is an increase in organic material; lime phosphate is deficient. The greater this imperfect development and the longer it continues, the more pronounced the signs of the disorder. It seems clear that if the disease occurred after the bones were developed symptoms of their disorder would be insignificant and of different character. This applies also to the nervous system. Nervous symptoms are more pronounced in all diseases of children because of the great instability of the nerve centers, due to their incomplete development. Lime starvation occurring at an age when the organs are developed would manifest itself by signs of different relative importance. Lime phosphate would not be needed for the development of the organs but, since a daily supply is necessary to repair physiological waste, a deficiency of this salt would nevertheless cause symptoms of impaired function. The name rickets is a misnomer, even for the disease in children, but suppose for illustration we imagine rickets to have developed in an adult. In such case bone symptoms would be practically absent; certainly far less pronounced than those arising from disorder of organs more immediately connected with vital processes. The changes in bone due to rickets are characteristic and, therefore, distinguishable from those due to other diseases. Unfortunately there are no signs by which muscular, nervous, and digestive disturbances due to lime starvation, unaccompanied by bone symptoms, may certainly be distinguished from those due to other causes. Nevertheless, such symptoms are known to occur in animals when there is an insufficient supply of lime.[2] My purpose is to suggest that the symptoms of lime starvation in man differ at different ages in the same way and for the same reason as in animals of different ages which are fed on food lacking in lime. In children, bone, muscular, nervous, and digestive symptoms occur; disturbances in bone and the nervous system most pronounced. In the more mature and adult, bones being developed, muscular, digestive, or nervous symptoms are most pronuonced and of different character because of the difference in the stage of development.

The condition which is recognized as preceding the active development of tuberculosis in the adult may be considered as due to lime starvation and its degree of severity varies just as it does in the disease of infancy.

2. Among inorganic substances lime salts appear

to be of special physiological importance. The formation of cells,[4] the clotting of blood and milk, nervous and muscular equilibrium,[1] depend upon their presence. Phosphate of lime forms a part of the normal structure of every organ in the body. Lime is being constantly discharged from the body as physiological waste material. It is, therefore, an essential food element. Three results must then follow an insufficient supply of lime. First, imperfectly developed organs. Secondly, lowered resistance to disease. Thirdly, lack of power to repair physiological waste; lack of power to repair injury. Imperfect structure of an organ leads to impaired function. Resistance to disease is a physiological function, therefore, imperfect organs must exercise imperfect resistance. Growth and repair are dependent upon cell formation. Cell formation will not take place in the absence of lime phosphate. Again, disease having been established, its extension is unobstructed because no plastic effusion is possible in the absence of lime phosphate. In other words, lime does not act as a poison to the bacillus in the treatment of tuberculosis, but serves to restore the normal protective function of the cells in producing a fibrosis at the point of irritation caused by the growth of the bacillus.

3. Lime starvation will result, (1), when there is a deficient supply of lime in the food. (2), when there is lack of absorption in a form suitable for cell-food. The first proposition needs no discussion.

Many substances are absorbed from the alimentary tract which are not of service for nutrition. After circulating in the blood they are excreted unused by the tissues. This appears to be the case with many inorganic salts taken with the food in excess of the needs of the body. It is conceivable that this may occur with the soluble salts of lime and to some extent with the insoluble phosphate. For, as has before been stated, it has been demonstrated that the alkaline blood-serum has the property of holding earthy phosphates in solution, but if the salts are not in organic combination it is difficult to suppose that the cells can appropriate them for food. To be available as nutriment they must be organically combined. Physiologists are agreed that the absorption of lime phosphate in an assimilable form, is best assured when in combination with proteid substances. As before stated it is suggested that the action of rennet in the stomach causes the chemical combination of lime phosphate and casein. It is admitted that the action of this enzyme results in a combination of these substances. The question has been whether the combination is mechanical or chemical. It is necessary for my purpose to show that this union is chemical. For otherwise, if mechanical only, the presence of lime must be looked upon as accidental and the action of rennet without importance for its absorption in an assimilable form. If, on the other hand, this combination is accepted as chemical then it is a fair inference that the action of rennet upon casein in the presence of lime must have an important bearing upon, if it is not essential for the further digestion and preparation of lime for absorption in a form suitable for the nutrition of cells.

Pure casein has a peculiar affinity for lime salts, particularly the phosphate, and combines with them chemically.[5] I have been unable to find a demonstration of the condition in which lime phosphate exists in paracasein. It apears to be an unusually difficult chemical problem. Various authors have, however, expressed very decided opinions. A few of the older writers state that the lime in the precipitate produced by the action of rennet on cow's milk (paracasein) is mechanically combined.[6] Their statements are not positive and imply doubt. The more modern writers all speak of paracasein as a lime salt of casein.[7] The conclusion is plainly justified that these authors regard the combination as chemical. If this conclusion be accepted it follows that in the absence of rennet the chemical combination of lime and casein will not take place. What is the influence which prevents the presence of rennet in the gastric secretion?

Rennet occurs in the stomach either in an active free state (as in calves and sheep) or in the form of an inactive zymogen which is transformed by acids into the active form.[8] In man it occurs in the form of zymogen. Its presence is never wanting in sucklings.[9] The formation of the ferment from the zymogen is entirely dependent on the presence of free acids so that in the absence of the latter from the gastric juice the free ferment is invariably wanting, even though the zymogen is present.[10] Almost all acids may be used for converting zymogen into the active ferment. The best is hydrochloric acid; the least effective, acetic acid.[8] In the stomach lactic acid and other organic acids also act as zymoplastic agents, in the absence of hydrochloric acid. Rennet zymogen is never absent from the stomach of man, even in pathological conditions, unless the secreting glands are destroyed, as in carcinoma.[11] It is evident, therefore, that insufficiency of free acid is the cause of deficiency of free rennet in the stomach. Calcium chloride also is said to activate zymogen.[12]

Absence of free hydrochloric acid from the gastric secretion has been reported in many diseases, particularly during fever and gastrointestinal disorders of both children and adults.[13]

Lime starvation must follow very quickly the complete absence of free acid; but because, in the majority of instances, lime starvation develops very slowly it is probable that variation in the degree of acidity is the commonest fault. The necessary daily amount of lime is small, especially in adults, and if there is enough hydrochloric acid secreted by the stomach, or organic acids taken with food, to bring about the combination and normal absorption of a small, though still inadequate amount of lime, evident symptoms of starvation will be delayed for a long time.* This would explain the exacerbations and remissions observed in the course of tuberculosis.

Rennet or its zymogen has been demonstrated in the stomach and many other organs of animals, birds, and fishes; in the digestive juices of carnivorous plants and in the fruit, leaves, seeds, or other parts of many trees, plants, and vegetables. It is found in bacteria and it is particularly interesting that this ferment has been prepared from the bacteria which occur in milk. This extensive occurrence of rennet in nature obviously points to some broader function of the enzyme than the clotting of milk.[15] If it could be demonstrated that the action of rennet upon casein from any source, as well as that contained in milk, in the presence of lime brought about a combination, it might be infer-

*Recent investigations make it appear that present methods for the determination of the degree of acidity of stomach contents are inaccurate.[14]

red that in this manner animals and plants received their necessary lime for growth and reproduction and a partial explanation at least, of the frequent occurrence of rennet given. But, even in this case, the explanation would not be complete. Vegetable casein is found in many plants (the leguminosæ), but it is difficult to believe that enough casein would be obtained from this source by fowl, for example, to satisfy their large demand for lime combination. If it could be shown that the action of rennet brings about a combination of other albumins and lime as well as casein and lime the reason for the presence of rennet in all these situations would be clear. So far, however, such combination has not been proven.

If it is true that lime starvation favors the growth and development of tubercle bacilli, it follows that rickets and conditions which lead to lime starvation, such as pregnancy, lactation, prolonged fevers, should show a marked tendency to be followed by infection with tubercle bacilli.

Tuberculosis is far more frequent during the time of the greatest growth activity, in the second to the third year than it is, for example, in the sixth to tenth year, in which growth has become slower.[16] The reason all rachitic children do not develop tuberculosis is because (1) they either do not become infected with tubercle bacilli during the active course of the disease, or (2) having become infected, their lime starvation is relieved and the further growth of bacilli checked, because the cure of rachitis must obviously also be the cure of tuberculosis. Rachitic children develop tuberculosis when infection takes place and their lime starvation is unrelieved or incompletely cured.

In the United States no race is exempt from rickets. In New York City the greatest susceptibility is among Negroes and Italians. Extreme cases of rickets are almost invariably in one of these nationalities. It is exceptional to see in a dispensary or hospital a child of either of these races who does not show, to a greater or less degree, the signs of rickets.[17] The mortality rate from pulmonary tuberculosis among Negroes, in the Negro block, is 3½ times that of the average for the city.[18] The mortality rate from pulmonary tuberculosis among Italians in New York City compiled by the Health Department, is said by a recent writer [19] to be misleading when employed to estimate the frequency of the occurrence of the disease in this race. He explains that pulmonary tuberculosis is very prevalent among Italians in New York City and "it is a well known fact that all adult Italians once affected by a serious disease, and so informed, board the first steamer and go back to Italy to die." This writer quotes the following as an illustration of how common the disease is among emigrants who return to Italy. "The total number of emigrants who returned to Italy in 1906 was 81,412, of whom 5.61 per 1,000 were cases of advanced pulmonary tuberculosis."

Another proposition is suggested, viz., the organ which suffers most from lack of lime in its organic structure at the time of infection should become the seat of tuberculosis. But there are no chemical observations showing which of the various organs of the body suffers most during lime starvation occurring at different ages.* When the active development of bone begins, its demand for lime becomes enormous, comparatively speaking, and, if there is a deficient supply, this organ must suffer most at this period. If infection with tubercle bacilli now takes place bone offers the least resistance and becomes the seat of disease. That bone tuberculosis does not manifest itself during the active course of the disease is explained by the fact that rickets, though prolonged, ends in recovery in the large proportion of cases so that the growth of tubercle bacilli, always slow, meets with great resistance in this situation and only manifests itself after a prolonged contest in those cases which end in incomplete recovery. In adults and children, during the first two years, the seat of election is the lungs. Rickets occurs most frequently between the ages of six months and two years. That the structure of the lungs especially is impaired during lime starvation and its resistance to disease lowered in consequence is suggested by the tendency of rickety children to develop pulmonary disorders. For example, as before stated, rickets in New York City is found more frequently among Negroes and Italians than any other race. In this city the mortality rate for bronchopneumonia is highest among Italians and Negroes. The Italian rate reaches the enormous height of 710 per 100,000.[21] Tuberculous meningitis is always secondary to other tuberculous lesions. Its frequency in children may be explained by the condition of the blood-vessels during lime starvation, to be mentioned later.

Every physician has witnessed the dire effect of pregnancy and lactation upon the course of tuberculosis. Pregnancy usually hastens the process, though it may be held in abeyance. After parturition the disease advances rapidly.[22] Pregnancy and lactation frequently introduce tuberculosis.[23] Certain of the specific fevers predispose to tuberculosis, among which measles and whopping cough stand prëeminent. Typhoid fever is thought by some to predispose to tuberculosis and influenza, variola, and syphilis are all believed to favor the development of the disease.[22]

Bovine Tuberculosis.—Dairy cows are kept in a constant state of either pregnancy or lactation or both. These conditions call upon the animal for large quantities of lime. During pregnancy the supply of lime necessary for the development of the fetus is large, and if the amount excreted in milk is added to this, the total becomes very large. For example, a cow yielding twenty quarts of milk loses about 480 grains of lime daily by this channel alone.

Because pregnancy and lactation are normal conditions and should not, therefore, produce disease, it is suggested that the cause of tuberculosis in these animals is due either to improper methods of breeding or an insufficient supply of proper food or both.

If pregnancy and lactation are factors in the causation of tuberculosis in dairy herds statistics should show greater prevalence of the disease in cows than in bulls and calves, and if their breeding and feeding is at fault, statistics should show greater prevalence of the disease among domesticated cattle of both sexes, among which such matters are controlled, than among cattle the food of which is abundant and of proper quality and their instincts, both as regards breeding and choice of kind and quantity of food, are unrestrained.

Certain facts should first be considered.

*Organic demineralization has recently been suggested, however, as a cause of tuberculosis.[20]

The extent of the occurrence of tuberculosis among animals is striking. The disease has been found practically in all species of animals, cold as well as warm-blooded. But there is a very great difference in the frequency of its occurrence in different species. With some it is common, with others rare. In other words, some species exercise great resistance to the growth of tubercle bacilli while others develop the disease on slight exposure to infection. Individuals of the same species differ in their power of resistance to the growth of tubercle bacilli just as species differ, though it may be in less degree. The power to resist the growth of tubercle bacilli when exposed to infection is therefore, as great, if not a greater factor in the spread of tuberculosis than the mere exposure to infection. For example, the classes of all species most affected are breeding animals and dairy stock.[24] Among ruminants tuberculosis is of much more frequent occurrence among bovines than among sheep and goats. Among bovines it is much more frequent in cows than in bulls and steers, and is very rare in calves, though the mothers may be tuberculous and the young are constantly exposed after birth. The number of tuberculous cows found in dairy herds is very large, but it is noticeable that even among these highly susceptible animals some individuals escape. Goats escape infection under surroundings and conditions most unfavorable for bovines. For example, "In Prussia, in 1899, in 381 slaughter houses 47,705 goats were killed. Of this number only 148 head (0.41 per cent.) were infected, either generally or locally. This result must be the more astonishing because the goats, with only a few exceptions, were kept under conditions eminently favorable to the spread of tuberculosis. Petersen, quoting these same figures, says that the goats ran freely in the cattle sheds, ate out of the racks of the tuberculous cows, and, owing to the well-known proclivities for mischief, took hay out of the mouths of the cattle, whereby they exposed themselves to the greatest possible infection."[25]

All statistics, both those of foreign as well as those of domestic slaughter houses, show that tuberculosis is more common in cows than bulls, steers, or calves. But the difference in the frequency of its occurrence in foreign slaughter houses and the large slaughter houses of this country is striking. For example, statistics from German abattoirs[26] show that 6.9 per cent. cows, 3.6 per cent. steers, 2.6 per cent. bulls and 1 per cent. of the young are tuberculous, while in this country under Federal inspection of 4,841,186 cattle slaughtered in 1900, 5,279 or 0.11 per cent. were sufficiently affected to cause condemnation of any part of the carcass.[24]

These facts may be explained by the hypothesis of lime starvation as follows:

The susceptibility of bovines to tuberculosis and the comparative immunity of goats may be explained by the difference in size of the animals.

In the artificial production of rickets in animals it is observed that large animals develop rickets much earlier and more certainly than small (large dogs in 22, small ones in 90, days). "A diet which supplies the need of lime for a small growing organism is not sufficient for a larger organism, since the latter does not take an amount of food proportional to his greater growth wherefore, he takes comparatively less lime. The animals of large build, therefore, demand a diet relatively richer in lime."[2] If, however, small animals are subjected to conditions which call for large outputs of lime, particularly if this loss is not supplied by proper food, these animals will also develop lime starvation. The great resistance to infection ordinarily displayed by goats has been mentioned and yet tuberculosis is occasionally found in herds of milch goats. For example, "There was a goat (in a large herd of 28 head) which had been brought for treatment and which, after its death, which soon followed, was found to be tuberculous to a high degree. This made it imperative to inoculate the remaining 27 head with tuberculin. In 18 of these, in consequence of the inoculation, a rise of temperature occurred of 1° to 2.5° C., and only in 9 did the increased temperature amount to less than 1° C. (0.6° to 0.9°). Because of this result 68 per cent of all the goats had to be retained on suspicion of being tuberculous, and only 32 per cent. were to be looked upon as probably free of tuberculosis. The owner could only make up his mind to have three slaughtered, of which two were suspected of being tuberculous and one was probably free of the disease, the result justifying the conclusion that the diagnosis was correct."[25] Milch goats if not restrained will breed twice a year and sometimes three times in a year. Such frequent breeding is recognized as injurious for the doe, but, if it were allowed to take place, and at the same time these animals obtained an insufficient supply of proper food, lime starvation would result and their resistance to infection destroyed. It is a fair inference that some such condition prevailed in the herd just described.

The insusceptibility of calves to tuberculosis has everywhere been noted. It has been recorded that calves produced by tuberculous cows, and left with the mothers until weaned, rarely show reaction to tuberculin and if separated from the mothers after weaning, as rarely develop tuberculosis.[27] Two explanations may be offered to account for the immunity of calves. First, they receive an ample supply of lime from the mother's milk. Secondly, rennet is found free in the stomach secretion of calves so that they are enabled to utilize all the available lime received. Possibly this may explain also the great difference between the human and bovine young in their susceptibility to tuberculosis.

It has been observed that beef cattle coming to our markets are singularly free from tuberculosis. As before stated tuberculosis is, however, found among them (.11 per cent.) and it is, therefore, manifest that the resistance of all classes, cows, steers and bulls, to the growth of tubercle bacilli is much greater in beef cattle of this country, than in similar animals of foreign countries. Most of the animals slaughtered for beef at the great packing houses of this country are raised on the plains and it is probable that their increased resistance is due to this fact. Of the many advantages for maintaining health which range cattle possess, such as less close association, wider excursions, etc., the greatest, it is but fair to assume, is the character of the food and the opportunity to exercise their unrestrained instinct in the selection of its kind and quantity.

Nature furnishes proof of the importance of lime, and normally supplies special sources of sup-

ply, during pregnancy. Theses stores occur in the form of osteophites and disappear after parturition. Pregnancy and lactation are normal conditions and it is incredible that under normal conditions they should lead to disease. Faulty digestion, as well as faulty diet, produce lime starvation in man. Among domesticated cattle the chief cause would appear to be defective methods of breeding and improper or insufficient food.

The following apparently disconnected subjects are briefly discussed because of their relation to lime and tuberculosis.

Hemoptysis.—Hemorrhage from the lungs is frequent in pulmonary tuberculosis. Repeated attacks occurring in the course of the disease make the prognosis unfavorable. Common as this symptom is it is not diagnostic of tuberculosis. Cases of hemoptysis have been recorded by careful observers which recovered and pulmonary disease did not subsequently develop.[28] Hemorrhage from the lungs may be explained by the disordered nutrition of the blood-vessels, to be mentioned later, caused by lack of lime phosphate. In the cases which recovered without subsequent signs of tuberculosis, lime phosphate was either restored before infection took place or in time to check the further growth of tubercle bacilli. Repeated and profuse attacks of hemoptysis indicate a severe grade of lime starvation and necessarily increase the gravity of the disease.

The Degeneration of Tubercle.—All tubercles undergo either softening, fibroid limitation, or calcification. Fibroid limitation and calcification are healing processes. Fibroid limitation means the growth of cells, which cannot take place in the absence of lime phosphate. Recent studies in pathological calcification show that the presence of fat is necessary for the deposition of lime.[29] Caseation of the tubercle, therefore, affords suitable soil for the deposition of lime salts and the formation of lime soaps and leads to healing by calcification. If too little lime is supplied, softening proceeds, and the disease extends.

Fat and Lime.—It is a universal practice to prescribe fat in the treatment of rickets, scrofula, and tuberculosis. The beneficial result from this practice is mentioned by all observers. The explanation is unknown. Allusion has been made to the relation between fat and lime in pathological calcification. The probabilities that the same relation obtains in normal calcification has been discussed but no conclusion reached.[30]

The Raw Meat Treatment of Tuberculosis.—The systematic, continued exhibition of raw meat in the treatment of pulmonary tuberculosis has been followed by good results. The purpose in mentioning it here is to suggest that the explanation of the good results of this treatment lies in the fact that raw meat is acid and contains rennet. Most meat is poor in lime, but one writer unconsciously supplied the deficiency in this regard in the treatment of his cases by adding, as he says, "one, two, or three eggs nature-swallowed like oysters" before each meal.[31]

Infantile scurvy and rickets frequently occur together in the same individual. Infantile and adult scurvy appears to be identical diseases. Scrofula and tuberculosis are associated. There is reason to believe that these diseases may all be merely different manifestations of the same fundamental disorder, viz., lime starvation.

The object in undertaking these experiments was to advance the dietetic treatment of tuberculosis and, while a discussion of the diseases just mentioned is not necessary for the fulfilment of this object, and I have no experience in their treatment to relate in support of the suggestion made, yet, in view of the importance of these diseases, a brief discussion of this conception of their origin does not seem inappropriate. It appears to the writer to be but carrying the hypothesis to a logical conclusion.

Three facts suggest a common cause for rickets and infantile scurvy. First, the two diseases are very frequently present at the same time in the same infant. Secondly, both diseases occur most often in artificially fed infants. Thirdly, the administration of acid food (raw milk and fruit juice) acts as a specific remedy in infantile scurvy.

1. In rickets, symptoms due to changes in bone, in scurvy, symptoms due to changes in blood-vessels and blood, are the most characteristic and striking. These differences are relative only, and due to differences in the degree of lime starvation. Scurvy is an acute disease and results when the supply of lime is entirely cut off. The blood is constantly losing lime by way of the intestines and kidneys. Tissues which are richer in lime yield part of their supply to the blood, but this source must soon fail, particularly in infants whose organs are still incompletely developed. All organs require lime phosphate for their normal development and the repair of waste. All organs, therefore, suffer when there is an insufficient supply, and the most urgent and striking symptoms will arise from derangement of the most vital organs. Nutritional derangements occur in the walls of the blood-vessels, in common with all of the organs of the body, and are quickly made manifest because the normal circulation of the blood is dependent upon their integrity. Changes in the walls of the blood-vessels allow the transudation of the blood. The most striking changes in the blood are caused by lack of lime, because the normal clotting of blood depends upon a normal supply of lime. As between the walls of the blood vessels and the composition of the blood, the vessels will suffer first because but one salt of lime, the phosphate, will answer for their nutrition. A number of lime salts will serve for the clotting of blood.[32] Possibly, even in the total absence of rennet from the gastric secretion, the soluble salts of lime, after absorption from the alimentary canal as inorganic salts, may be combined in the blood current to a slight extent, because rennet has been demonstrated in blood-clot.[33] Rickets is a chronic disease and is the result of a lesser degree of lime starvation. In this disease the walls of the blood vessels are affected, for it has been demonstrated that the heart, arteries, and capillaries are enlarged,[34] but the changes are not extensive enough to allow transudation of blood. From this reasoning it follows that it is possible for rickets to occur without scurvy but inconceivable that scurvy should occur without some degree of rickets. It will be remembered that, in the absence of hydrochloric acid, organic acids may serve to activate rennet zymogen. The treatment of infantile scurvy by fruit juices or raw milk, or both, has probably prevented in many instances the farther development of rickets.

2. The natural food of infants is milk. In ad-

dition to lime and casein normal human and cow's milk contains citric acid which, it is assumed, has power to activate rennet zymogen.* Rickets and scurvy develop when the secretion of hydrochloric acid has diminished and the infant is fed milk which has been prepared in such a manner that its property of activating rennet zymogen is destroyed. This follows too great dilution with water, the addition of alkalies, and heating. Diminished secretion of hydrochloric acid follows some of the many influences which cause fever in infants, such as improper feeding, gastrointestinal catarrh, bronchopneumonia, the exanthemata, etc.

Citric acid is destroyed when milk is heated. It combines with lime and falls as the insoluble citrate of lime.[36] The action of rennet is delayed or entirely destroyed, 1, when raw milk is diluted with water, the particular effect depending upon the degree of dilution; sixty per cent. destroys the action. 2. The action is destroyed when more than thirty per cent. lime water is added to raw milk; when more than fifteen per cent. is added to heated milk. 3. When milk is heated; so-called sterilization. It is interesting, that raising the acidity of largely diluted raw milk and largely diluted sterilized milk, without the addition of lime, causes a clot with rennet in normal time.

The following tables show the action of rennet after adding very weak solutions of dilute (10 per cent.) hydrochloric acid to either raw or heated milk.†

RAW MILK DILUTED 50 PER CENT. WITH WATERY SOLUTIONS OF HYDROCHLORIC ACID OF VARIOUS STRENGTHS.

	Time of Clot. (Body temperature)
Plain water.	100 minutes
Strength of acid solution:‡	
1/10 of 1 per cent. acid solution.....	5 "
5/100 of 1 per cent. acid solution.....	5 "
2/100 of 1 per cent. acid solution.....	5 "
1/100 of 1 per cent. acid solution.....	25 "
Action of nitric acid the same.	

HEATED MILK (ARNOLD STERILIZER 20 MINUTES) DILUTED 50 PER CENT. WITH WATERY SOLUTIONS OF HYDROCHLORIC ACID OF VARIOUS STRENGTHS. ACID SOLUTIONS ADDED AFTER HEATING.

	Time of Clot. (Body temperature)
Plain water did not clot at end of 20 hours.	
Strength of acid solution:‡	
1/10 of 1 per cent. acid solution.....	5 minutes
5/100 of 1 per cent. acid solution.....	10 "
2/100 of 1 per cent. acid solution.....	1 hour 5 min.
1/100 of 1 per cent. acid solution.....	2 hrs. 55 min.

When raw milk is diluted 50 per cent. with the strongest watery solution of hydrochloric acid mentioned above (1/10 of 1 per cent.) and raised to a temperature of 100 deg. Fahr., curds are at first produced but are so fine as to offer no obstruction to the passage of the mixture through a rubber nipple. After a few miutes these curds are dissolved by the hydrochloric acid and disappear.

*It has been suggested by others that citric acid may be the antiscorbutic element of fresh milk[35].

†Attention is directed to the fact that length of time required to produce clotting of milk by rennet, in a given series of experiments, is only relative. Milk from different dairies, milk from the same dairy on different days and different parts of the same day, difference in strength of solution of rennet used, will all show difference in time results. In the above experiments, conducted in the writer's laboratory, the same milk and same solution of rennet were employed. As soon as milk was received in the morning experiments were begun and completed as soon as possible.

‡The percentage of acid refers to the watry solutions, not to the mixture of solution and milk.

In the light of the foregoing the course of rickets toward spontaneous recovery is explained by the intake of acid foods. Improvement usually begins about the time that undiluted raw milk, meat, vegetables, and fruit are added to the child's diet.

Adult Scurvy. The conception that adult scurvy is caused by lime starvation receives support from (1), symptoms which point to changes in bone, (2), lack of power to repair injury, and (3), the character of foods which act as specific remedies in the treatment of the disease.

1. In advanced cases (adult scurvy) necrosis of bones may occur, and in young persons even separation of the epiphyses. There are instances in which the cartilages have separated from the sternum. The callus of a recently repaired fracture has been known to undergo destruction.[32]

2. Traumatism, even slight, is often followed by serious results. In confirmed scurvy the slightest pressure suffices to open the skin and give rise to an ulcer which increases rapidly in size. Sometimes the disorganization of the flesh is sufficiently complete to expose the bones and produce caries.[37] In other words repair is impossible without lime phosphate.

3. The number and variety alone of antiscorbutics is impressive. They appear to have but one characteristic in common, viz., acidity. A few such as raw meat, figs, pineapple, paw paw, artichokes, contain rennet in addition.

To one whose attention has never been drawn to this subject the small number of foods which fail to show an acid reaction is surprising. Salt pork is the only meat so far examined which failed to give an acid reaction, either before or after cooking. No exceptions are found among vegetables or fruits. The degree of acidity varies, of course. For example, lettuce is very faintly acid, while romaine is very decidedly so. Among fruits the most potent antiscorbutics are the most acid. Foods which are acid and contain lime phosphate and casein, such as undiluted raw milk, or, are acid and contain both lime phosphate and rennet, such as raw meat and blood together, are certain antiscorbutics.

Cases of scurvy have been reported in which analysis of stomach contents showed no free hydrochloric acid.[38]

Scrofula is regarded as a manifestation of incompletely cured rickets or of lime starvation occuring after the greatest activity of development of bone has taken place.

It would appear from the foregoing that lime starvation may be a menace from the time of conception to extreme old age and, as compared with those made in the first part of this paper, much broader deductions drawn as to its effects, viz.: First, lime phosphate is essential for the growth of cells. It is, therefore, necessary for the normal structure of organs and the repair of injury. Secondly, without the action of rennet the combination of lime and casein suitable for the physiological needs of the body is not produced. Thirdly, lack of such lime combination is the cause of many diseases.

THE INCANDESCENT AND THE ARC LIGHT IN MEDICINE.

DIFFERENTIAL INDICATIONS FOR THEIR USE.

BY A. D. ROCKWELL, M.D.,

NEW YORK.

NEUROLOGIST AND ELECTROTHERAPEUTIST TO THE FLUSHING HOSPITAL.

THERE is no more important and efficient method in its relation to therapeutics than the application of light and heat, and although much has been written about it, and much use has been made of it, yet, from the standpoint of those who from personal experience fully appreciate its value, it seems surprising that there is not a more universal recognition of its varied therapeutic properties.

In the few remarks that follow on light therapy it is not my thought to include the whole of phototherapy. I do not propose to discuss the Finsen Light which is a very important part of phototherapy, but for the information of those who have a confused idea of what constitutes the Finsen light, and imagine that it is a very simple and easy thing to get, a word may fitly be said. The Finsen light, whether derived from sunlight or the electric arc light, exerts only actinic or chemical effects. In Finsen's original installation, an arc light of 20,000 candle power was used, and the intense heat thus developed had to be absorbed by an elaborate cooling process, before the ultraviolet rays were available for practical and efficient use. The original Finsen lamp required 80 amperes of current and sixty minutes of exposure, but with simplified apparatus good work can be done with five amperes and less exposure. Strictly speaking, the essence of the Finsen light is not light at all, for the ultraviolet frequencies of infinite rapidity are no more visible than the still higher frequencies of the *x*-ray, or the far lower frequencies that we appreciate as sound or heat. The effect of the so-called Finsen light then is local and superficial, of remarkable value, in the treatment of skin affections, but of little worth in deep seated morbid conditions.

The ultraviolet ray has no power of penetration. It is immediately absorbed by the blood, and even when the parts are rendered anemic by pressure or by adrenalin and cataphoric action, its penetration is still comparatively superficial. Used alone and

uncombined it exerts no general constitutional effect, and acts only on the periphery, but as Finsen demonstrated is invaluable in dermatological cases and especially in the treatment of lupus. It cannot be too often repeated that the difference in forms of physical energy is one of degree rather than of kind. The three things that go to make up a complete light treatment, or phototherapy, are the heat, light, and chemical rays which are simply different rates of vibration. Sound, which is a lower rate of vibration, we do not regard of therapeutic value, but as vibrations increase in frequency and decrease in length we get the heat rays, then light (the visible spectrum) until finally we enter the region of the invisible (the ultraviolet), and beyond this the *x*-ray. Light, heat, and chemical energy constitute the trinity of phototherapy. These combined effects are undoubtedly represented best by the rays of the sun—which when concentrated act more powerfully than those from any artificial source, but for obvious reasons their general and successful utilization is impracticable.

The two available artificial sources of this method of treatment are the incandescent lamp and the arc light, either of which are superior both in physiological and therapeutic effect to the ordinary hot air bath, for the reason that the latter is more depressing and far less penetrating than radiant heat, and is without chemical activity. In the administration of light energy, one should bear in mind an important fundamental principle, viz., that resistance develops energy, a principle as striking on its moral and intellectual side as on its physical. Electricity, for example, is of value therapeutically only as it meets with resistance, and in the same way, light cures disease, only as it meets the resistance of the human body, and is transformed into radiant energy. The rays from a powerful incandescent or arc lamp readily penetrate the skin, but in overcoming the deeper and denser structures are converted into heat. Heat, therefore, is one of the principal therapeutic factors in the use of the electric light.

It may be observed further, that radiated heat, as developed by the incandescent, and especially by the arc light, results in a more rapid and powerful dilatation of the superficial vessels than the action of simple hot air, and this relaxation of vessels, because of no appreciable heating of the surrounding air, can be continued indefinitely. These light rays exert a remarkable stimulating effect upon the peripheral nerve endings, and may be utilized to excite perspiration more quickly than any other method The superior efficiency of this form of radiant energy is increasing oxidation, and tissue changes are evidenced in the elimination of carbon dioxide. As indicated by this elimination, oxidation goes on far more rapidly under the influence of radiant light than of simple hot air. Another well recognized and important factor in the light treatment, more especially the arc light, is its action on the blood. The hemoglobin carrying power of the red corpuscles is demonstrably increased, and through the influence of its invisible rays upon microorganisms we get pronounced bactericidal effects.

My first experiences along this line were with the incandescent lamp, not the ordinary incandescent light bath, made up of many small electric bulbs enclosing the body of the patient, but of a single lamp of 500 candle power.

Placed within a cylindrical metal hood and suspended by a convenient mechanism, the light can be easily applied to any and all parts of the body For the relief of pain and especially in the treatment of neuritis it is invaluable.* I even went so far as to say that in the relief of local painful conditions and in its general constitutional influence it was superior to the arc light. In this I believe I was mistaken. After a more extended experience in its use I do not hesitate to assert, that while the arc is quite as valuable as the incandescent light for the relief of pain, its influence upon defective blood and skin conditions is far superior. From what has already been said as to the composition of these two manifestations of light, it is not difficult to understand why this may be so. Both are forms of radiant energy, but in the incandescent or leucodescent lamp, the glass globe effectually intercepts the chemical rays, while the arc light with no intercepting barrier gives the full value of the concentrated solar ray. While, therefore, theoretically, it is no difficult matter to decide upon the relative value of these two forms of light and to rule as to some differential indications for their use, practically it has not been quite so easy. Many cases had to be treated, some by one method, some by the other, with results on the whole seeming to indicate the greater efficiency of the arc light, but it was not until the two methods were successively used in the treatment of the same patients that the superiority of the one method to the other became strikingly manifest.

Of several cases thus alternately treated, the one here given may be regarded, it seems to me, as especially suggestive and conclusive, and is the basis and inspiration of what precedes.

Case.—Miss H., aged 16 years, I first saw November 13, 1908. Her general appearance was one of extreme inanition and profound anemia. The whole course of the spine was extremely tender to the touch, and she suffered from such severe and constant pain in the region of the ciliospinal center, and down the right arm, and in a lesser degree in the left, that hypodermics of morphine had been a necessity for the past two months. The menstruation was irregular and scanty, and unusually light in color, but painless. Other symptoms there were of occasional hysterical attacks, associated with vertigo and double vision, but for our purpose those given are sufficient. It may be said that among various remedies, iron had been freely taken, but with little if any result. Under the light treatment from the incandescent lamp the patient began to improve. It was applied to the neck, body and arms, the seances being gradually increased from ten minutes to half an hour. Twenty applications were administered at intervals of a day, and for three weeks the improvement was progressive. She was able to dispense with the morphine and the pain in a great measure subsided. During the following three weeks, however, she did not improve further in any marked or satisfactory degree, and for the time being discontinued treatment, yet feeling that much had been accomplished. Some two months subsequently she came again with somewhat increased pain in neck and arms, but not sufficiently severe to compel a resort to morphine. In other respects she was about the same as when last seen—very weak and anemic. The arc light was now used instead of the incandescent, and with results that were soon manifest. The pain very quickly disappeared, more quickly, without doubt, because of the results obtained with the former treatment, but the point of

*See article on Phototherapy in Neuritis, Medical Record, November 9, 1907.

special interest was the ready response in a constitutional way to the newly instituted treatment. The appetite and digestion both improved markedly. There was increase of weight and strength, and three weeks after beginning the second course of treatment with the arc light there was a recurrence of almost normal menstruation. The improvement in the hemoglobin carrying power of the blood was indicated by a gradual disappearance of her extreme pallor.

Briefly stated then, the superiority of the arc light to the incandescent in the treatment of certain local surface conditions, and conditions constitutional and general is due to the fact that with light and heat are combined the subtle chemical reactions which are wanting in the other. The arc light represents all the rays of the spectrum as does the sun itself, and practically it is nothing but sunlight. Fortunately, however, for our therapeutic purposes, it is far more controllable than sunlight, and can instantly be made intense or mild, concentrated or diffused, and even the different light rays selected or excluded at will.

The Sydenham, Madison Avenue and Fifty-eighth Street.

THE GENERAL DEATH RATE FROM MALIGNANT GROWTHS IN THE PRINCIPAL AMERICAN CITIES, 1883 TO 1907.

By ROY F. EDWARDS,

NEWARK, N. J.

Now that the medical profession and sanitary authorities have become conversant with the cause and means of prevention of the great white plague, there is probably no other scourage to which the human race is subjected that is receiving more universal consideration than cancer. In several of our cities cancer hospitals have been established and, while the data presented in the various reports appear to indicate an advance in the methods and results of treatment, usually operative, still there is little doubt but that the mortality from this disease is on the increase.

Of the 375,990 deaths among males reported in the registration area of the United States in 1907, cancer caused 11,800 deaths, or 3.1 per cent., and of the 311,044 deaths of females 18,714, or 6.0 per cent., were classified as due to cancer and malignant tumors. In the aggregate, cancer, as a cause of death, ranked eighth, causing 4.4 per cent. of the total mortality. These figures indicate an increase of 2.3 per 100,000 of population in the cancer mortality rate over the preceding year, 1906, for the same area.

In compiling the data included in the following tables, all of which were obtained directly from the reports of the local bureaus of vital statistics, the causes of death considered as cancer were the same as those indicated in the International Classification of Causes of Death which was adopted by the Census Bureau for the compilation of the mortality statistics of 1900, and which has subsequently been quite generally adopted throughout the registration area.

The cities included in these tables comprise practically all of those for which the returns are available for this consecutive period of years. The data are complete, with the exception of those from Cleveland for the year 1883, New Orleans for the year 1883 (for which no vital statistics are available), Nashville for the years 1883 and 1884, and Savannah for the year 1899. Unfortunately, the returns from Baltimore were not reported by color until the year 1891*, which necessitated its inclusion among the Northern and Western cities.

The following table illustrates the increase in the death rates from cancer as returned for the thirty-five cities under consideration.

For the Northern and Western cities there has been a gradual increase in the death rates, vary-

*Annual report of the Sub-Department of Health of Baltimore for the year ending December 31, 1904, p. 24.

TABLE I.—MORTALITY FROM MALIGNANT GROWTHS IN THIRTY-FIVE AMERICAN CITIES—1883–1907

Death Rates per 100,000 of Population

Years	Northern and Western Cities				Southern Cities, "White"				Southern Cities, "Colored"			
	No. of Cities	Aggregate Population	Deaths	Rate	No. of Cities	Aggregate Population	Deaths	Rate	No. of Cities	Aggregate Population	Deaths	Rate
1883	27	6,097,585	2,960	48.5	5	225,013	89	39.6	5	153,738	60	39.0

1907	28	12,524,695	9,686	77.3	7	676,134	612	90.5	7	373,909	227	60.7

ing from 48.3 per 100,000 of population in 1885 to 77.3 in 1907. With the exception of the years 1885, 1888, 1889, 1893, and 1902 there has been an increase over the preceding year. In the white mortality from cancer in the seven Southern cities there has been an even greater increase, ranging from 39.6 per 100,000 of population in 1883 to 90.5 in 1907. Sixteen of the twenty-five years show an increase over the preceding year. Especially noticeable is the steady increase during the decade ending with 1907, for which period the figures should be the most trustworthy. The same may be said of the colored mortality in the Southern cities during the last decade; only there are pertinent reasons for doubting the reliability of these returns, with the possible exception of those for Washington and New Orleans.

Table II illustrates the death rates from cancer in each of the thirty-five cities, individually and in the aggregate, for the quinquennial periods. Of the twenty-eight Northern and Western cities two have more than doubled—Haverhill, with an increase in the death rate of 67.4 per 100,000 of population, and San Francisco, with an increase of 52.3. In the cities having a population of 500,000 or more in 1907, the increase in the death rates have been as follows: Chicago, leading with 30.9; Baltimore, with 29.2; St. Louis, with 25.2; Philadelphia, with 24.6; Boston, with 22.7; Manhattan and the Bronx, with 21.0, and Brooklyn, with 20.6. In eleven of the twenty-eight Northern and Western cities there has been a steady increase over each preceding quinquennium, and in the aggregate the increase has been consistent. New Bedford, with only 0.8 per

*Four years only.
†Three years only

100,000 of population, shows the smallest rate of increase; Cambridge is next, with a rate of 17.1, and Gloucester is third with a rate of 17.3. Of the white mortality from cancer in the Southern cities, Nashville shows the greatest increase with a rate of 62.1; Memphis second, with an increase of 39.8; and Richmond third, with an increase of 34.8. Nashville and Washington are the only cities which show a consistent increase over each preceding quinquennium. Of the colored mortality from cancer in the Southern cities little can be said except that, generally speaking, the colored race is not as susceptible to cancer as the white race. In the aggregate there has been an increase of 12.2 per 100.000 of population.

In considering the death rates from cancer three very important factors present themselves—First: how far is the rate affected by the inclusion of persons coming to the cities for treatment, resulting in ultimate failure, but whose deaths were reported in the city records. This is amply illustrated by the city of Boston. During the eight calendar years ending in 1907 the death rate from cancer was 76.4 per 100,000 of population. Among residents and those whose residence was not determined the rate was 65.9, making a reduction of 10.5, or about 14 per cent., in the local death rate from this cause. If this be true of most of the large cities, which is very probable, a considerable reduction would occur in the rate, affecting the later years more than the earlier. Second: how far does improper diagnosis and false or careless methods of death registration affect the rate. The assumption is that this would only have its effect upon the earlier periods in question because of the fact that the medical profession has made rapid strides, both in the matter of accurate diagnosis and also in the more accurate reporting of the causes of death. How much this would affect the rate it is impossible to say. Third: what effect has the age distribution of the population upon the rate. As cancer is distinctly a disease of the older ages (in the registration area during the period 1903 to 1907 about 80 per cent. of the deaths from cancer occurred at ages 45 and over) it seems reasonable to assume that allowance for this factor would cause no material depreciation in the general rate.

Finally, it seems safe to assume that the mortality from cancer is on the increase and has been so for the last quarter of a century in this country.

DISEASES OF THE EYE IN PELLAGRA.*

By A. B. CLARKE, M.D.,

PLANTERSVILLE, S. C.

In diseases of the eye occurring in pellagra, I find no peculiarities in the symptomatology, characteristic appearances, or complications, save only they are very prone to exhibit the same cycle, as it were, a recrudescence in early spring time, and, as summer progresses, make recovery.

My observations and findings have been primarily upon the rice field negro, who has been inured to hardships, poorly educated, and equally poorly nourished, seldom able to read, and when he has visual disturbances, attributes it to local conditions. My patients have invariably given the history of using damp meal, grits in lumps in bags which have been wet, buying week's supply and leaving in the sack openly exposed to vermin and dew, many times sours and eating sour corn-bread.

My attention was first directed to this disease in 1906. The patients gave me history of rheumatic pains, general malaise, sensation of heat in the esophagus and region of the kidneys, radiating to the hands and feet, noticeably the palms and soles. One child has spastic paralysis. All complained of vertigo, neuralgic pains in the posterior aspect of the neck. The backs of the hands and feet were "sunburnt," the skin being swollen, tense, burning, and itching; severe stomatitis noted. The reflexes were exaggerated, and the patients had insomnia, anorexia, and erythema with petechiæ occuring at times, also small oval blisters, even bullæ, which upon breaking down left indolent ulcers. The chief physical symptoms were delusions, apathy, melancholia, disorientation with symptoms of dementia præcox. In two of my cases between the fingers were cracks extending to the metacarpal bones and exposing the ligaments. The tongue is heavily coated with a dark streak in the center, notched around the edge, and very red; or it is smooth and denuded of epithelium, or marked by deep fissures. I have never seen any change in the hair and nails. All give digestive disturbances and lack of appetite. As the disease progresses, the mental disturbances increase. The patients are dull and apathetic, slow in speech, listlessly tired, or suffer from a dread of persecution, or exhibit suicidal tendencies. Many of the patients complain of pains in the eyes, one of diplopia, and others of various symptoms.

Case I.—Man 42, negro. Had been working timber and living upon a diet of grist and cornmeal mush, crackers and cheese, all of which he stated had become mouled and soured, as he had no place to keep them. Had marked pellagra symptoms. He was suffering from ectropion, both eyes being affected with slight conjunctivitis. Iris was dilated. Very little photophobia, cornea, aqueous, and lens clear, vitreous slightly hazy, choroid showing marks and scars of atrophy. Arteries pale, veins thick and heavy. The other eye was normal, consensual reaction from left to right, but not from right to left. I made several further attempts at examination, but patient was in a cachectic condition and refused, dying in seven days after last attempt to view the fundus.

Case II.—Child 6½ years, boy, negro; epiphora both eyes, marked pellagra patient, talked incoherently all the time, had 3/5 degree fever (axilla). The mouth, tongue, and nares were raw. Mother stated that child's eyes became sore every spring, which suggested vernal catarrh. He had marked conjunctivitis with small granulation, which resisted all treatment, cornea, aqueous, lens, and vitreous were clear. Opthalmoscopic findings: Fundus showed a dark black spot similar to retinitis pigmentosa, only limited to about 4 mm. around the nerve-head, and involving the macula region. There was no evidence of choroiditis, nor were these dark areas in any other part of the fundus. Mother stated that child's eyes had been sore in the spring time for three or four years, when his hands and feet became sunburnt. His vision had become worse this time. (From this child I recovered uncinarias upon two occasions.) Child's hands, feet, arms, legs, and nape of neck in horrible condition, extremely emaciated. He died in five days after my seeing him. The parents refused autopsy, nor would they allow me to remove one of his eyes.

*Read at the Pellagra Conference, Columbia, S. C., October, 1909.

Case III.—Man, 36 years, negro. Working in swamp, making shingles, living on grits and condensed milk; he would make enough at night to do the next day; sometimes it would sour in the pot, he said, but if boiled again it was fit to eat. It had given him indigestion, he stated. Both hands, arms, and legs presented distinct line of demarcation with round ulcers, some confluent with irregular edges, and edema. Patient was painfully emaciated, complained of pains in the eye with burning sensation and failing vision. Upon examination I found fundus apparently normal; optic nerve was pale, almost white, there was beginning nerve atrophy. Patient was to return in 14 days, but was unable to do so, dying in 19 days after last visit.

Case IV.—Girl, 17, negress. Anemic enlarged glands, cervical and epitrochlear. In the right eye the cornea was hazy, with small ulcers, iris irregularly dilated, posterior synechia, aqueous hazy, vitreous muddy, there was a large fundal hemorrhage on the temporal side. Patient stated she was not aware that she was blind in that eye. Had floating bodies. I was unable to get any detail of fundus. Left eye normal. In the inner canthus of each eye was a small papilla which exuded watery substance upon being punctured. Patient came regularly for four weeks, but became rapidly worse, and died in 11 days after last visit.

Case V.—Women, 42, negress. Second year had "sunburnt" hands with sore mouth, vertigo, had lost considerable flesh and had grown melancholy with hallucinations. Iritis in right eye three weeks. She gave a history of living on damp grits and damaged meal. Upon examination, hands and feet were seen to be desquamating in layers, leaving a shiny, tense, and in places raw bleeding surface beneath. Lips and tongue were denuded. She suffered from insomnia and had no memory. Opthalmoscope gave no fundal lesions. Patient is recovering.

Case VI.—Woman, 26, negress. First year mouth became sore and denuded, bright red in appearance, distinct erythema; complained of pains in the eyes, smarting, and burning. Patient came every other day for two weeks, and each morning had a film of bluish tint over the cornea in each eye. At the end of six weeks she stated that her eyes gave her no further trouble. Physical condition was improved, and mentally she was slowly making progress. Opthalmoscopic examination showed the nerve head normal, arteries very small, veins enlarged, small hemorrhages in veins to nasal size in physiological cup. This patient gave positive history of having lived on damaged meal.

In presenting these histories, I have refrained from repetition as much as possible, also from citing pellagra symptoms. The class of persons who suffer are they who lack nitrogenous food. Many exist upon rice, grist, and potatoes, and a little cheap poor grade pork, termed "second" or "butts." They need meat, red meat, and a variety of vegetables. In four out of seven cases that I examined I found uncinaria. The treatment has been supportive and nutritious. Tonics in increasing doses of tincture of the chloride of iron up to 30 minims three times a day; Fowler's solution to point of tolerance as high as 24 minims three times a day; cod liver oil and eggs; acetate of lead and opium for the diarrhea; phosphoric acid and fish diet, also oat meal; strychnine or tincture of nux vomica; milk in abundance. I find local applications of practically no value. From my observation, I am of the opinion that pellagra is a trophoneurotic condition, involving the entire sympathetic system; not an autointoxication, but secondary to the ingestion of a fungi or ferment which cause catabolic changes.

Longitudinal Hypertrophy of the Cervix Uteri as a Complication of Pregnancy and Labor.—Andrea Boni gives the histories of three cases of longitudinal hypertrophy of the cervix complicating pregnancy and labor, which have been observed by him, and a short résumé of forty-one cases described in medical literature. The seriousness of this complication depends on the amount of hypertrophy that occurs. In slight cases the hypertrophy does not prevent the normal delivery of the child. In some cases it is so extreme that the cervix forms a tumor which protrudes from the vulva and becomes ulcerated or even necrotic. In these cases delivery is only possible by means of operation. The subjective symptoms are disturbances of urination, weight in the pelvis, leucorrhea, and ulceration. The etiology includes previous hypertrophy of the cervix. Other cases originate in the pregnancy itself. Still others result from prolapsus of the uterus and involve chiefly the cervix. The microscopic changes in the organ are these: the muscular and connective tissues are increased in amount proportionally to the amount of hypertrophy; in the fourth month the elastic tissue is much hypertrophied, but at the end of pregnancy it is in relatively normal amount; the glandular tissue has undergone cystic degeneration; the vascular tissue is that which is most affected by hyperplasia, and hypertrophy. This increase in vascular tissue is an exaggeration of a process normal to pregnancy. Normally there is a great amount of hyperemia, and irritation results in greater congestion and new formation of blood-vessels. If the organ projects from the vulva there is still greater irritation. In cases of marked hypertrophy the best treatment is amputation of the cervix. In lesser degrees it is in order to wait and see if simple dilatation of the cervix will not enable the delivery of the child. If the fetus is dead embryotomy is in order.—*Gazzetta Internazionale di Medicina.*

Effect of the X-Rays in Infantile Leukemia.—G. Zamboni says that the *x*-rays do not benefit the condition of young infants affected with myelogenous leukemia, the only modification that is produced being reduction of the white corpuscles and the myelogenous cells. In lymphatic leukemia the results are always unfavorable. In myelogenous leukemia of later childhood the results have been better, although an entire cure has not been obtained. The diminution of the white blood cells and of the abnormal cells is due to the leucolytic effect of the rays. The diminution of red blood cells and hemoglobin is due to the direct hemolysis caused by the rays. The reduction of the size of the spleen is caused by a double action of the *x*-rays, by the neutralization of the pathogenic agent, and by causing necrobiosis of the new-formed elements that have emigrated. It is best to use applications of the rays that do not penetrate deeply, and to limit them to the splenic region, with short sittings and long intervals. In cases of long standing with cachexia the rays should not be used, since they make the condition of the patient worse. The rays do not act as a radical cure of this condition, but only as a palliative measure, which will relieve certain symptoms.—*Rivista Internazionale di Terapia Fisica.*

Sixty Cases of Antituberculous Vaccination.—Ezio Calcaterra tells his experience in the antituberculous vaccination of sixty cases with a variety of materials. The material used contained antigens and precipitins of tuberculosis, and they were inoculated into persons sick with a variety of diseases. There were ten positive cases of tuberculosis, and ten babies under six years, of whom six had tuberculosis of the surgical type. The skin was scarified, and after vaccination the lesions covered with aseptic dressings and guttapercha tissue. A local reaction was frequent at the point of vaccination, occurring in thirty-nine cases. A zone of hyperemia formed with a papule, which rapidly became pustulous and formed a small erosion. If the vaccination was not deep no scar resulted, but if it extended into the lower layers of the skin a scar remained. There was some spontaneous pain. The lymphatic glands became moderately swollen, and tender; there was no reaction in the tuberculous lesion in those cases in which tuberculosis was shown to be present by the physical signs. Fever was rare, occurring only in the tuberculous subjects. The tuberculosis patients gave a more severe reaction than other patients. Quite small doses of the vaccinating material seem to be sufficient to produce active immunization.—*Annali dell' Istituto Maragliano.*

MEDICAL RECORD.

New York, December 18, 1909.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE ARMY.

In his annual report to the Secretary of War for the fiscal year ending June 30, which has just been published, General Torney treats of a number of interesting topics. We have had occasion several times to deprecate the severe physical test to which the officers of the army are submitted once a year, and we are greatly pleased to find that General Torney is also opposed to them. He says that four years ago the Surgeon-General recommended that a progressive system of physical training under the supervision of medical officers should be adopted by the army, so that its personnel might be at all times physically fit for active service. This recommendation was approved by the Secretary of War but instead of its being carried into effect, a severe physical test was established for the officers with the ostensible object of maintaining a "physical condition which would enable them to be always fit for active field service." This the test does not accomplish and General Torney says it is believed that it "not only fails in this purpose but may result in serious damage to elderly officers. Its defect is that it requires officers to be fit only once a year." The suggestion made by General Barry in his report of April 1, 1909, is concurred in, that the test ride be modified in its requirements for those serving in the tropics and that for officers of 62 years or more the taking of the test ride be optional.

An experiment has been made, or rather begun, to determine the efficacy of antityphoid vaccination in the army. During the summer of 1908 Major F. F. Russell was sent to England to study the methods in use there in the prevention and stamping out of typhoid epidemics both in the army and among the civil population. Upon his return his report and recommendations were submitted to a board made up of six members of the Army Medical Reserve Corps in addition to General Torney and Major Russell. This board found that the method of antityphoid vaccination is useful and harmless, and recommended that the practice of voluntary vaccination be introduced at once. A room in the Army Medical Museum was fitted up as a vaccine laboratory, and by the end of February of this year a considerable amount of vaccine was ready for use. Many volunteers offered themselves, and up to the date of the report 830 completed record cards had been received. The greater number of the vaccinated received three doses, fewer received two doses, and about 5 per cent. only one dose. The amount of protection given by the vaccination, as judged by the quantity of antibodies in the serum of the vaccinated, was very great, exceeding in some cases that following an attack of the disease. "The procedure has been introduced so recently that it is not possible to form any very exact idea of the protection given from statistics showing the morbidity and mortality from typhoid, but it is at least interesting to note that no cases of fever have appeared among the 830 who have been treated, although they have been exposed equally with the rest of the army."

Another point of interest touched upon is the effect of uncinariasis on the general health of the army. In December, 1908, Capt. Joseph F. Siler reported from the recruiting depot at Fort Slocum, N. Y., that out of nineteen Southern recruits examined sixteen were found to be infected with hookworm. A later report from Capt. Siler covering 124 Southern recruits showed 109 infections. These figures excluded men who had been many years away from their Southern homes or who had lived only a short time in Southern cities. Major Chamberlain, in observations made at Jackson Barracks, Miss., found that out of 44 Southern-bred recruits 68 per cent. were infected; out of 57 Southern-bred soldiers in first enlistment 54 per cent. were infected, and out of 34 Southern-bred soldiers in second, or subsequent, enlistment only 15 per cent. were infected. In the army of Cuban pacification, of the 24 cases of infection reported, where the length of service of the individual was given, 16 were in their first enlistment, 4 were in the second, and 4 had served more than two enlistments.

The fact is apparently shown by these statistics that the infection, which is necessarily mild, otherwise the recruits could not have passed the physical examination, tends to disappear spontaneously, and General Torney does not think that it is a very serious factor as regards the health and efficiency of the army, however vast its economic importance may be in the Southern States.

In discussing conditions in the Philippines, the Surgeon-General mentions an investigation being conducted by the Board for the Study of Tropical Diseases of the value of orange-colored underwear in excluding the actinic rays. Since the publication of Major Woodruff's book on "The Effect of Tropical Light on White Men," the theory that the actinic rays of sunlight, and not the heat, are the chief cause of the injurious effects of a prolonged stay by Northerners in the tropics has been much discussed. An interesting test has now been undertaken. This plan, which was approved by the division commander, provided for a test upon approximately 1,000 men, half of whom were to wear the colored underclothing, the other half to wear white underclothing of similar weight, to serve as controls. Organizations having over a year to serve in the division were selected to furnish the subjects for the test. A medical officer was designated at

each of the posts, who was to have charge of the details of the experiments, and who was to stay with the selected organizations during its course. The plans for the experiment contemplate a comparative record of strength and blood-pressure tests of pulse, respiration, and temperature after fatigue, practice marches, or drills, of all symptoms referable to the effect of the sun after exposure thereto, and a measure of anemia by red and white blood corpuscle counts, differential leucocyte counts, and hemoglobin estimations. Special tests will be carried out upon a small number of men in addition. Experimental work upon the effects of heat and light upon small plant and animal life is also contemplated. The experiment is now in full progress, and it is thought that some conclusive evidence will result.

It is gratifying to learn that the "increased inducements to enter the Medical Corps, provided by the act to increase the efficiency of the Medical Department, approved April 23, 1908, and the recent increase in pay for the army at large have resulted in a considerable increase in the number of candidates appearing at the preliminary examinations for that corps. . . . The year before the approval of this act but 10 physicians were obtained to attend the Army Medical School preliminary to being commissioned in the Medical Corps if they demonstrated their fitness therefor. Last year, 33 candidates were secured and 29 were finally commissioned as compared with 10 the previous year." The number of medical officers in the service is, however, still 135 below that which will be allowed under the present law when the total increase is legally available, which will be in 1911, and in order to fill the service by that time 60 new medical officers would have to be commissioned each year for the next three years, which is practically impossible.

THE FEDERAL BUREAU OF HEALTH.

During the political campaign, which resulted in the election of Mr. Taft to the Presidency of the United States, the medical profession took a quiet part in politics, a part of sufficient activity, however, to procure the embodiment in the platform of both of the leading parties of planks advocating the uniting of all matters connected with the health of the nation, under a single organization backed by Federal authority.

In his recent message to Congress President Taft discusses the subject as follows: "For a very considerable period a movement has been gathering strength, especially among the members of the medical profession, in favor of a concentration of the instruments of the National Government which have to do with the promotion of public health. In the nature of things, the Medical Department of the Army and the Medical Department of the Navy must be kept separate. But there seems to be no reason why all the other bureaus and offices in the general Government which have to do with the public health or subjects akin thereto should not be united in a bureau to be called the 'Bureau of Public Health.' This would necessitate the transfer of the Marine-Hospital Service to such a bureau. I am aware that there is a wide field in respect to the public health committed to the States in which the Federal Government cannot exercise jurisdiction, but we have seen in the Agricultural Department the expansion into widest usefulness of a department giving attention to agriculture when that subject is plainly one over which the States properly exercise direct jurisdiction. The opportunities offered for useful research and the spread of useful information in regard to the cultivation of the soil and the breeding of stock and the solution of many of the intricate problems in progressive agriculture have demonstrated the wisdom of establishing that department. Similar reasons, of equal force, can be given for the establishment of a bureau of health that shall not only exercise the police jurisdiction of the Federal Government respecting quarantine, but which shall also afford an opportunity for investigation and research by competent experts into questions of health affecting the whole country, or important sections thereof, questions which, in the absence of Federal governmental work, are not likely to be promptly solved."

The words of the President speak for themselves as to the need of a Federal Bureau of Public Health and require but slight comment here. The question of States rights has been overcome for the Department of Agriculture, and it can surely be waived in this instance also. Mr. Taft says that the Public Health and Marine-Hospital Service should be transferred to the new bureau. This splendidly organized and efficient national institution should in fact be the foundation stone upon which the new structure will be built. Possibly the most feasible procedure would be to make no great fundamental change, but merely to widen the scope and power of the present organization and to place all matters of national hygiene under the direction of the surgeon-general. Later we may hope for a Federal department of hygiene, whose secretary will have a seat in the cabinet and also for the adoption of a national bureau of examination and registration and the abolition of the farce of individual State boards. These will be the natural outcome of such a bureau, and will be of the greatest benefit to physician and layman alike. They must, however, come gradually and the first step should be the broadening of the Public Health and Marine-Hospital Service into a strong, competent, active Bureau of Public Health. It is to be hoped that the present Congress will give heed to these words of the President, and by a proper organization of health matters will do for our citizens at least as much as it has done for our crops and our cattle.

PSEUDOBULBAR PALSY.

The disordered emotional manifestations which accompany it might lead an inexperienced observer to believe that purely functional causes were at the root of the form of disability known as pseudobulbar palsy. This syndrome, however, is the result of bilateral interruptions in the corticobulbar projection fibers. The lesions, though sometimes extensive, are usually of the lacunar type, and small, though

numerous. It is seldom that they do not produce some modification of control of the limbs in addition to the preponderant interference with the power of moving the lips, tongue, palate, pharynx, and larynx, which is the source of dribbling of saliva, regurgitation through the nose, the choking, and characteristic dysarthria and vocal monotony of these patients. The crural dyskinesia consists mainly of *marche aux petits pas* with its shuffling, hesitating, short steps slightly spastic in type, the doddering gait of the senile. The reflexes are usually slightly exaggerated, though clonus and the Babinski sign are rarely present. As a rule, the patient can make quite extensive, though uncertain, movements of his legs when urged to do so: it is only in the walk or other automatic acts that the movements are so restricted. When the lesions occur below the red nucleus they may cause the mesencephalic tremor, which will be evident in the arm by an uncertainty of movement somewhat resembling that of multiple sclerosis. These cases are less common than those originating in the centrum ovale, and tend to lack the power of manifestation of emotional expression, rather than to show the inapposite outbreaks characteristic of the former lesions.

The probable explanation of this difference is that, as Pagano believes, the reactions of emotivity are determined by the corpus striatum or other basal ganglia, and pass through the rubrospinal and perhaps vestibulospinal tracts. A mesencephalic lesion, therefore, prevents the passage of ganglionic impulses; whereas a lesion in the centrum ovale merely cuts off their cortical inhibition; it hence prevents the regulation of their activities by the higher centers, and permits of the spasmodic laugh and cry so characteristic of the upper type of pseudobulbar palsy. Some clinicians, notably Pierre Marie, have believed that a unilateral lesion could produce this syndrome, but their conclusions depend upon incomplete post-mortem examination; for Compte has shown that a complete series of brain sections always reveals bilateral lesions. It is possible, however, that a mere apraxia, affecting the face, mouth, tongue, palate, etc., may have simulated a true palsy; and in that case the lesion need have been only unilateral, though some of the cases adduced have shown right-sided lesions, whereas apraxia is the result of lesions of the left hemisphere except in the left-handed. Others have maintained that lesions of the putamen were the true cause; and that these organs were really subsidiary centers for associating the special acts of articulation and swallowing, and that their destruction must entail pseudobulbar palsy. This contention seems to be disproved by two cases which Déjerine observed, in which there was found destruction of the outer portion of both lenticular nuclei, in each case without any pseudobulbar symptoms during life.

Fatal Poisoning by Quinine.

While symptoms of an excessive use of quinine, in the form of tinnitus, dizziness, deafness, skin eruptions, fever, and mild psychoses are comparatively frequent occurrences, instances of fatal poisoning by the drug are decidely rare. A case reported by Baermann in the *Münchener medizinische Wochenschrift* for November 9, 1909, in which the idiosyncrasy to the drug was so marked that two doses of seven and a half grains each caused death, is of interest as a medical curiosity. The patient was a Chinaman living in Sumatra who was suffering from tertian malaria. The first dose of a half gram of quinine sulphate in solution caused a disappearance of parasites from the blood. The second dose was vomited at once. A half hour after the third dose, given on the second day, the patient broke out into a profuse sweat, collapsed, and had severe epistaxis, controlled only by tampons. First unconscious, he was later mentally confused. Three hours after the onset he passed a half liter of fresh blood *per rectum*, had hematemesis, and slight hemoptysis. With a second intestinal hemorrhage the patient died. The autopsy, made shortly after death, showed purpuric swellings covering almost the entire body. In the parietal peritoneum, mesentery, omentum, and intestines were fresh hemorrhages. The pleural and pericardial cavities contained blood, and collections were found throughout the entire alimentary tract, both within the lumen and intramuscularly. Sanguineous deposits were discovered in the tissue of the liver, spleen, pancreas, and kidneys. Cerebral and meningeal hemorrhages were noted. Beyond these widespread local hemorrhages in practically every organ of the body there were no pathological changes seen. Especially poisonous properties or contaminations of the drug could be excluded, as many other patients were being supplied from the same bottle without deleterious results. The only conclusion to be drawn seemed to be that the patient died as the result of an extraordinary susceptibility to quinine.

News of the Week.

The National American Red Cross Association held its fifth annual convention in Washington December 6, 1909. President Taft presided and presented to Lloyd C. Griscom, former Ambassador from the United States to Italy, a gold medal from the Red Cross, a silver medal to Miss Katherine B. Davis and one of the same metal to Samuel L. Parrish. All these medals were given for zeal shown in the Italian earthquake days. The association voted also to give gold medals to W. Bayard Cutting and Lieutenant-Commander E. R. Belknap, U. S. N., for handling the Red Cross affairs at Messina. There were few changes in the executive officers. President Taft was again elected *President*, and Robert W. De Forest *Vice-President*. Charles D. Norton, First Assistant Secretary of the Treasury, was made *Treasurer* instead of Beekman Winthrop, and Charles L. Magee was made *Secretary*. Lloyd W. Bowers, Solicitor-General of the United States, was made *Chancellor*.

The Nobel Prize Awards recently announced in Christiania include Professor Emil Theodor Kocher of Berne, as recipient of the prize for medicine.

Berlin Vacation Courses.—The Berlin Docents Union announces that the next series of vacation courses in medicine will begin on February 28, 1910, and will last until March 26. The prospectus of lectures and other information may be obtained by applying to Herr Melzer, Ziegelstrasse 10-11 (Langenbeck Haus), Berlin.

Condemnation of the Roosevelt Endurance Test.—Surgeon General Torney, U. S. A., in his annual report criticises the endurance tests of army officers instituted by President Roosevelt. He advocates in the place of one annual test the systematic physical exercise of all officers. To make this possible every staff and line officer doing office work should be supplied with a good riding horse and one orderly, as is done in Europe. He also advises that the test ride be modified for officers serving in the tropics and for those over 62 years of age. In several cases the single violent test for elderly officers not in condition has caused physical injury.

Professor Jacques Loeb of the University of California has been offered the chair of experimental biology in the University of Budapest.

Spinal Anesthesia.—Since his arrival in New York Dr. Jonnesco, the Roumanian surgeon, has had several opportunities to demonstrate his method of spinal anesthesia, described in a recent issue of the MEDICAL RECORD. Among the institutions in which the operations were performed were the Hospital for Ruptured and Crippled and the New York Post-Graduate Hospital. It is reported that that the results of the trials have not been so uniformly brilliant as to arouse any wild enthusiasm.

Playground for the Foundling Asylum.—Announcement has just been made of the gift by Mr. Charles M. Schwab to the Sisters of Charity of St. Vincent de Paul for the use by the New York Foundling Asylum of one of the most beautiful and well-equipped playgrounds in the neighborhood of New York City. The tract of land is on Staten Island one-half mile from Huguenot, on the shore of Raritan Bay. The playground will be known as Richmond Beach Park. It has a water frontage of 1,700 feet, and from the beach the ground rises sharply to a considerable height. A pavilion has been constructed to accommodate 1,000 children, and large bathing houses have been made. The tract contains a large fresh water lake. The grounds have been beautifully laid out, with macadamized roads and a complete system of drainage.

New Polyclinic Hospital.—Plans have been completed for the new building for the New York Polyclinic Hospital to be built on West Fiftieth street. Work will be begun in May and the building is to be ready for occupancy by the summer of 1911.

Gift to Jefferson Medical College.—The valuable laboratory apparatus of the late Professor Henry C. Chapman, professor of the institutes of medicine and of medical jurisprudence in Jefferson Medical College has been presented to the college by his widow.

Charitable Bequests.—By the will of the late Mrs. Catharine Boyle of Philadelphia the sum of $5,000 is left to St. Mary's Hospital.

Coeducation Abolished.—It is announced that in the future no more women will be admitted to the South Carolina Medical School. Those now in attendance will be allowed to continue to graduation, when coeducation will cease.

Ulster County Tuberculosis Hospital.—The Board of Supervisors of Ulster County (N. Y.) have taken advantage of the Hamilton-Whitney bill to establish a hospital for the cure of tuberculosis. The plan is to take over the day and night camp for consumptives, established last summer by the local committee on tuberculosis of the State Charities Aid Association, and convert it into a permanent hospital.

Dr. John M. Swan has been elected associate professor of clinical medicine in the Medico-Chirurgical College of Philadelphia.

Tropical Medicine.—The New York Post-Graduate Medical School is establishing in its new buildings a full equipment of wards and laboratories for the teaching of tropical medicine. The department is being conducted under the cooperation of the U. S. Army, Navy, and Public Health services, who detail officers from their respective medical corps to assist in the conduct of the laboratory and clinical courses.

Guild of St. Luke.—A number of physicians met at Cathedral College, New York, on Wednesday evening of last week and organized a society, under the above title, to be in affiliation with similar societies already existing in France, England, and other countries. The object of the society is the study of the ethical, moral, and historical problems connected with the practice of medicine. The following officers were elected: Dr. Charles E. Nammack, *President;* Drs. Thomas Addis Emmet and José M. Ferrer, *Vice-Presidents;* Drs. Thomas F. Reilly and James J. Walsh, *Secretaries.*

Fairs in Aid of Hospitals.—A bazaar was held on Tuesday of this week at the Plaza Hotel for the benefit of the Babies' Day Hospital. During the latter half of the week a fair was held at the Waldorf-Astoria Hotel in aid of the Lebanon Hospital.

The Harvey Society.—The fourth lecture of the Harvey Society will be delivered by Professor Carl G. Huber of the University of Michigan, on Saturday, December 18, 1909, at 8:30 P.M., at the New York Academy of Medicine. Subject: "Renal Structure."

Medical Society of the County of Kings.—The Section on Pediatrics, at its 100th regular meeting, elected officers for the ensuing year as follows: *Chairman,* Dr. Walter D. Ludlum; *Vice-Chairman,* Dr. Sigmund Beck; *Secretary* and *Treasurer,* Dr. Alexander Spingarn.

The Vernon County (Mo.) Medical Society, at a meeting held December 2, 1909, elected the following officers: *President,* Dr. Lemore, of Nevada; *Vice-President,* Dr. O. P. Farrington, of Moundville; *Secretary and Treasurer,* Dr. V. O. Williams.

Obituary Notes.—Dr. ALFRED D. KAHN of Chicago, Ill., died December 2, 1909, aged 40 years. He was a graduate of the Rush Medical College in 1898, and was an instructor in that institution and on the staff of the Michael Reese Hospital. He was also a member of the Board of Education of Chicago. He was a member of the Chicago Medical Society, the Illinois State Medical Society, and the American Medical Association.

Dr. WILLIAM H. SHEETS of Jeffersonville, Ind., died at his home December 1, 1909, aged 78 years. After being admitted to the Methodist University Dr. Sheets took up the study of medicine and graduated from the Cincinnati College of Medicine and Surgery in 1862. He was at one time secretary of the Board of Health and was a member of the Clark County Medical Society and the Indiana State Medical Association.

Dr. G. P. HYNDMAN of Minot, N. D., died No-

vember 26, 1909, aged 35 years. He was a graduate of the Detroit Medical College in 1898.

Dr. Thomas B. Hicks of New Haven, Ill., died December 2, 1909, aged 68 years. He was a graduate of the Cleveland Medical College in 1872.

Dr. Andrew C. Mailer of Depere, Wis., died December 3, 1909, aged 56 years. He was a graduate of the Rush Medical College in 1878, and of the Bellevue Hospital Medical College in 1882. Dr. Mailer was a member of the Brown County Medical Society, the States Medical Society of Wisconsin, and the American Medical Association. He was mayor of his town from 1892-1894, and State Senator from 1896-1902.

Dr. Donald Churchill of Providence, R. I., died November 28, 1909, as the result of blood poisoning, aged 39 years. He was a graduate of Harvard University in 1893, and the Harvard Medical School in 1899. He was on the surgical staff of the Rhode Island Hospital and a member of the American Medical Association, the Massachusetts Medical Society, the Rhode Island Medical Society, the Providence Medical Association, the Clinical Club, and the Rhode Island Hospital Club.

Dr. Stephen D. Harrel of Lamar, S. C., died November 30, 1909, aged 48 years. He was a graduate of the Medical College of the State of South Carolina in 1890.

Dr. Lewis Edgar Klinefelter of Rockford, Ia., died at his home November 26, 1909. He was a graduate of the College of Physicians and Surgeons of Chicago and a member of the Floyd County Medical Society and the Iowa State Medical Society.

Dr. Elizabeth G. Monville died at Philadelphia on December 5 at the age of 33 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1909.

Dr. Frank Rieser died at Reading, Pa., on December 5, at the age of 79 years. He was graduated from the Pennsylvania Medical College in the class of 1852. He practised his profession in Chester for ten years, and then went to Reading, retiring three years ago.

Dr. Benedict Dallas Bucher died at Lebanon, Pa., on December 8, at the age of 58 years. He was graduated from Jefferson Medical College in the class of 1871.

Dr. Frank E. Risley of Brooklyn, N. Y., died at his home December 10, 1909, aged 55 years. Dr. Risley was a graduate of the New York Homeopathic Medical College, and was an attending physician of the Cumberland and Prospect Heights hospitals.

Dr. Isabella M. Wilson of Middletown, N. Y., died at her home November 30, 1909, aged 59 years. She was a graduate of the New York Medical College and Hospital for Women in 1894, and for several years practised in New York City.

Dr. George S. Aldrich of Ludlow, Mass., died at his home November 21, 1909, aged 27 years. He was a graduate of the Tufts Medical College in 1907 and afterwards interne in the Cambridge Hospital.

Dr. Hiram H. Wright of Detroit, Mich., died at his residence November 24, 1909, as the result of typhoid fever, aged 46 years. Dr. Wright was a graduate of the University of Toronto, and held the degree of the Royal College of Physicians of London. He was a member of the Wayne County Medical Society, the Michigan State Medical Association, and the American Medical Association.

Obituary.

FERDINAND C. VALENTINE, M. D.,

NEW YORK.

Dr. Ferdinand C. Valentine died at his country home in Belle Harbor, L. I., on Monday of this week, of arteriosclerosis and dilatation of the heart. He had been suffering for some time and had been in Europe since August, part of the time at Nauheim, seeking relief; he returned only a few days before his death. He was born in 1851 and was graduated from the Missouri Medical College, St. Louis, in the class of 1876. Early in his professional career he went to Central America and was at one time Surgeon-General of the army of Honduras. Later he was in London for a time, and then settled in New York, where he devoted himself especially to genitourinary practice. He was a fellow of the New York Academy of Medicine, a member of the New York County and State Medical Societies, of the American Medical Association, and the Medical and Pharmaceutical Faculties of Guatemala, Honduras, and San Salvador; corresponding member of the Société Française d'Urologie, and of the Deutsche Gesellschaft für Urologie; honorary member of the Société d'Urologie Belge, and ex-president of the American Urological Association.

Dr. Valentine was a man of rare and attractive personality and of a broad culture, a linguist of talent, and a writer of clear idiomatic English. At one time indeed he was tempted to devote his life to literature, but concluded in the end to remain in the practice of medicine. He was devoted to his profession, which he regarded as a sacred calling, one to be practised for the good of his fellow man, and to be studied as the greatest of sciences. And he had the joy that comes as a reward of honest work as well as the satisfaction which the true physician feels in relieving suffering.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TUBERCULOSIS EXHIBITION—LEADLESS GLAZING—GENERAL MEDICAL COUNCIL—CANCER INOCULATION—COLITIS, HEMORRHAGE AND APPENDICOSTOMY—X-RAYS IN DIAGNOSIS—OBITUARY.

London, November 26, 1909.

A tuberculosis exhibition has been opened in the Western District of London, organized by the National Association for the Prevention of Consumption. It is somewhat on the lines of the work done by the association in Ireland, but on a more extended scale. The Chelsea Town Hall has been taken for the purpose, and has been well fitted up for the display. On the walls are graphic pictures, showing, among other things, the benefits of sleeping in well-ventilated rooms and the need of dusting all rooms properly. Models of back-to-back houses which have been demolished; photographs of "cozy, stuffy" rooms in which some ignorant people delight, contrasting with well-ventilated ones; models, too, of sanatoria, an open-air church, garden shelters made from old church pews, of hospital wards, and other instructive exhibits.

The opening ceremony (on Tuesday) was performed by Lord Cheylesmore, who said that as chairman of Brompton Hospital he was interested in everything connected with the treatment and prevention of consumption. The exhibition at the Eastern District of the metropolis had been visited by 50,000 people, and he thought such exhibitions did an enormous amount of good, teaching people that the disease was infectious and to a certain extent it could be prevented. It was twenty-five years since he was elected on the board of

the Brompton Hospital, and during those years the whole treatment of the disease had been revolutionized. The object in those early days was to keep every room and corner in the building at 63°, winter and summer. To-day the hospital was the most breezy and draughty place he ever entered. Every window was open night and day, and he was afraid to state the temperature in the early morning lately. His Lordship then explained the system of "graduated work" at the Frimley Sanatorium, and went on to say that the best results had followed the "contact system" by which the Medical Officer of Health was notified when a consumptive was admitted to the hospital, and so had the opportunity of visiting the patient's home and seeing whether others in his family showed any signs of the disease. If this plan were followed throughout the Kingdom it would do much to prevent the spread of the disease. Lord Cheylesmore then put in a plea for the soldier. He had himself served in the Guards for forty-four years. In the early days the disease was rife and attributed to the night air when on sentry-go. But that was outdoor treatment. He thought now the disease was due to the barracks, which had not been brought up to date, and the War Office might do much by increasing the cubic air space. He was on a committee for the relief of veterans, and the other day had to visit several workhouses, which were all much better than barracks. He thought a grateful country should do something more for consumptive soldiers and suggested that a sanatorium might be built for them.

Another exhibition of medical interest is also being held, viz., one of Leadless Glaze, the object being to convince the public of the evils of employing lead on account of the injury to the workers and that there is no longer any necessity to use lead in the process. Specimens of table and toilet ware of the finest kinds—some costly, others quite inexpensive—are on view in great variety. Ornamental pottery and porcelaine, artistic tiles and household and sanitary ware of all kinds can be compared. One stall, that of the ladies' organizing committee, contains only pieces which they guarantee have been constantly used in their own households for definite periods. This stall seems a great attraction, so much good may result.

Sir Donald Macalister opened the winter session of the General Medical Council on Tuesday with a presidential address. It was not a more lively performance than usual and seems, like the rest of the proceedings, to excite no interest. He mentioned that an additional representative of the registered practitioners has been approved, so that at the next election they can have four members instead of three. As the fact has been known for months, it is devoid of interest, as, for the most part, are all the doings of the council, for it cannot be denied that this body has been a great disappointment to all medical reformers. The winter meeting is chiefly devoted to the investigation of alleged offenses. The penal committee first considers these with the advice of the solicitor, and in any which they report a *prima facie* case the council inquires into it, the accused person being heard by himself or his legal adviser.

The report of the education committee was presented. It recommends the division of the curriculum into two parts of two and one-half years each. It has been found that the curriculum is so overcrowded that only about 13 per cent. of the students can qualify in the five years. Further discussion gave rise to various suggestions and is not yet concluded.

On Monday evening, *i.e.* the evening before the opening of the session, the three direct representatives attended a meeting of the London branch of the British Medical Association and gave what they called an account of their doings to "their constituents." This is quite a new departure, and only proves once more the accusation that the British Medical Association has always aimed at controlling the elections and even the representatives. It has largely succeeded in engineering the matter to the great annoyance of that large section of the profession which sees through the doings of the clique and regards them as a scandal and a disgrace, but will not rouse itself to put an end to them.

In the Pathological Section (Royal Society of Medicine) Dr. M. Haaland had a paper on inoculation of cancer in which he directed attention and the ease with which spontaneously occurring carcinoma could be grafted upon the same animal as against its inoculation in other animals, either in health or affected with the spontaneous disease. This suggested that better results might be obtained by transplantations from the same person than from the use of tissues from others. So there was great danger to the patient in operations, if cancer cells were disseminated in the wound, though there is not much danger of the transference of the disease from one person to another, which seems to show that the conditions of growth of sporadic tumors are specific to each.

Dr. J. A. Murray showed specimens from a cow affected with adenocarcinoma of liver, from which ingrowths passed into the portal vein. He could not accept the theory that the blood contained substances inimical to the growth of cancer cells. For an embolus to grow it must become vascularized from the wall of the vessel. If this failed the growth aborted. He showed a rat in which pulmonary carcinomata had followed intravenous injection of cancer.

Dr. B. J. R. Russell showed a specimen from a mouse in which carcinoma cells, experimentally grafted, established the growth of a sarcoma, the cells of the latter being furnished by the tissues of the animal.

In the Clinical Section, after the cases referred to in my last week's letter, Dr. Hale White read a paper for which he was jointly responsible with Mr. Lockhart Mummery and Dr. Bruce Porter. It was the story of a case of pneumococcal colitis with hyperpyrexia, in the course of which severe hemorrhage was treated by appendicostomy.

It is not often that colitis due to the pneumococcus is detected during life and the diagnosis confirmed by bacteriological examination. For this reason the case is interesting. It also illustrates the successful treatment of hyperpyrexia by cold sponging. Attention was drawn to the good effect that followed the running of cold water through the colon. Before the case was under their care cold enemata had been used without diminishing the bleeding. Hazeline was added to the injections for four days before operating, but without effect. After all other measures failed appendicostomy was done as a means of running cold water through the colon and the case showed the value of this plan in arresting the hemorrhage. Subcutaneous injections of oil were given as a means of nutrition.

Mr. Charles Symonds said he had seen the operation do harm, so it was necessary to consider how soon it should be resorted to.

Dr. White replied there could be no question of the great benefit in this case.

At the Hunterian Society on the 8th inst. Dr. A. C. Jordan gave an interesting address on the value and limits of *x*-ray diagnosis, illustrating his statements by some eighty slides. He maintained that in phthisis every case could be detected as soon as physical signs could be made out and that the extent and distribution of the disease could be ascertained. Further, he held that the disease might often be diagnosed by *x*-rays before any physical signs could be made out. The *x*-rays were also of great value in examining the gastro-intestinal tube. For this purpose carbonate of bismuth should be used suspended in milk or water with flour, sugar of milk, or other innocent substance. The subnitrate must not be used, as nitrous acid might be liberated, from which indeed fatal results had occurred in Germany. But from two to four ounces of carbonate could be safely employed. When the mixture was swallowed in esophageal stricture it was seen in bulk in the dilated part above and only a thin stream trickled through into the stomach. So when there was a pouch the screen showed the mixture flowing into the stomach, but leaving a portion in the pouch above. The shape of the stomach in health varied with its contents, as well as with the pressure upon it by the other viscera in different positions. When a patient with a dropped transverse colon contracted the abdominal muscles the colon would rise—sometimes to its normal level. It was suggested that such cases might be improved by massage, exercise, etc. When no rise of the colon appeared the stomach was usually dropped also. Manual pressure upon the abdomen might in such cases cause the rise. For such a case a well-fitting belt was suggested as likely to be beneficial. When the colon was greatly distended by gas it appeared as a clear band across the abdomen, which was a sort of dark ground. One of Dr. Jordan's slides showed this condition in a baby with congenital dilatation of the colon.

Dr. George Lichtenberg has died at the age of eighty-three at his country house in Norfolk, to which he retired several years ago. He graduated in 1851 at Göttenberg, became a Member of the London College

of Physicians in 1860, and in 1863 of the College of Surgeons. He was elected on the staff of the German Hospital here, and in due course became the senior surgeon. He enjoyed a consulting practice in the city, living in Finsbury Square for many years. He contributed some papers, mostly surgical, to the societies and journals.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

GENERAL RACHIANESTHESIA—ISOLATION OF TYPHOID PATIENTS —SURGICAL TREATMENT OF A NOT INFREQUENT CAUSE OF STERILITY—THYROID NEUROARTHRITISM AND ITS TREATMENT —INAUGURATION OF THE AMERICAN HOSPITAL—THE ULTRAMICROSCOPE AND CINEMATOGRAPHY.

PARIS, November 30, 1909.

PROFESSOR JONNESCO of Bucharest brings up again the method of general rachianesthesia which Bier of Berlin and Rehn of Frankfort condemned. The method of Jonnesco has two fundamental principles—puncture of the spinal canal in any location, and the addition of strychnine to the anesthetic. The latter may be one of the cocaine substitutes. Spinal puncture is not dangerous; it should be made usually between the twelfth dorsal and the first lumbar vertebræ. The neutral sulphate of strychnine added to the anesthetic solution preserves all its analgesic power, while removing its toxic action on the bulb. Thanks to this power it is that anesthesia is not dangerous. The solution employed should not be sterilized, for sterilization takes away part of its properties, and the preparation should as far as possible be made freshly. Jonnesco believes that rachianesthesia is absolutely safe. It never causes death nor gives rise to accidents of immediate importance or late seriousness. It appears to him infinitely superior to anesthesia by inhalation. Being produced by the surgeon himself, it does away with an assistant who is often unskilful and always irresponsible. He is persuaded that spinal anesthesia will be the anesthetic method of the future.

Vallin believes that typhoid fever is much more frequent in France than in the other northern and central countries of Europe. Isolation of typhoid patients has been practised for only a few years past; it should be carried out more frequently. Convalescents from typhoid fever having all the appearance of a complete return to health may for some weeks or months still be carriers of the germs in their intestines, the gall-bladder, or the urinary bladder. Before sending a patient back to the family life, especially returning him to the village life, he should be submitted to a medical examination, and we should instruct the carriers of germs that they may be a source of danger to their neighbors, just as much as the carriers of tuberculosis. Widal estimates that in every hospital service there should be several beds reserved for isolation of typhoid patients, for hospital contagion exists, although rarely; it is observed in the occupants of the next beds and among the nurses who care for typhoid patients; it is carried by the objects that have been used by the patients, and by the hands. Every person who has touched typhoid patients should undergo a careful disinfection of his hands, and every object which has been used by typhoid patients should be specially reserved for them. It should be noted that certain persons, during a longer or shorter time after typhoid fever, throw off in their feces typhoid bacilli which may propagate the disease anew. Unfortunately, at present we are hardly able to prevent the carriers of germs from doing harm to their surroundings. They may be cautioned to disinfect their stools, but such a method is difficult to practise for several months or years; for some it is impossible to accomplish isolation.

Pozzi showed that a very frequent cause of sterility in the female consists in a conical-shaped cervix, the narrowness of the os, and an exaggeration of the normal anterior curvature of the uterus. In such cases dysmenorrhea is the rule. Every menstrual period is a painful crisis; sterility is the rule on account of the narrowness of the external os, of the curvature of the canal, and the difficulty of drainage of the cervical mucus. The operation which is generally practised in these cases is gradual dilatation with a haminaria tent, or immediate dilatation with bougies, but its result is very transient. This is why Pozzi advocates an operation having a permanent effect, and one which he calls stomatoplasia with rupture of the commissures. He rapidly dilates the cervix by means of Hegar's bougies, and separates the two lips of the cervix by a double section of the commissures, so as to open it like a duck's beak. Suture is preceded by freshening of the bleeding parts, which amounts to a true submucous section of the cervix. Finally, he practises an immediate and entire occlusion of the operative wound so as to prevent stenosis and infection. Doleris considers Pozzi's operation as altogether excellent, and thinks that we should have recourse to it when simple, slow, progressive dilatation of the uterine cavity has not given good results.

Thyroid neuroarthritism and its treatment was considered by Leopold-Levy; it represents a common affection which causes a whole series of troubles and brings about bad function of the thyroid gland. The results of thyroid treatment of neuroarthritic cases are excellent; migraine, chronic rheumatism, gout, asthma, dermatoses, enteritis, and neurasthenia are all benefited by thyroid treatment. The diagnosis of neuroarthritism is made by the circumstances in which the various lesions develop, by the study of the temperament of the subject; thyroid instability gives rise to special syndomes. Treatment should make use of a preparation of the fresh glands obtained by cold desiccation in a vacuum; the doses should be proportioned to the condition of the patient. Certain adjuvant mediations are indicated practically in the form of classic drugs, iodine, arsenic, and phosphorus.

On October 28 there took place the inauguration of the American Hospital, situated at Neuilly, by his Excellency the Ambassador of the United States. The French Government was represented by M. Doumergue, Minister of Public Instruction. This hospital is essentially a charitable institution, due to the initiative of a certain number of Americans resident in Paris, who have grouped themselves together for the purpose of founding a charitable institution in conformity with the French laws of associations. This hospital will receive indigent and sick Americans; they will be cared for freely, but the fortunate may be received if they wish and be cared for with the most favorable surroundings. No fixed charge is made to the patients, but according to their means they may give a sum which will be used for the general expenses of the hospital. This is essentially an American institution, modeled after the great institutions of the United States. In spite of its small size, it is quite complete in its appointments and does credit to its founders.

Comandon has had the happy idea of applying the ultramicroscope to cinematography. At the Academy of Sciences Dastre gave his experiences, which have met with the greatest success. Up to this time it has been possible to study germs only in very small numbers and stained; to-day, with the ultramicroscope, we may seize them alive and the invisible world is cinematographed. Comandon has publicly shown, amid the applause of his audience, trypanosomes as the living agents of sleeping sickness, spirochetes of syphilis, with their quick and lively movements; finally, the normal and pathogenic parasites which constitute the intestinal flora.

[Dr. R. L. Watkins of this city described an apparatus of this kind in the *Scientific American* of July 31, 1897; the invention of M. Comandon is therefore not novel.—ED.]

Progress of Medical Science.

Boston Medical and Surgical Journal, December 2, 1909.

Interstitial Pregnancy.—F. W. Johnson reports the case of a woman who had borne one child seven months before she came under his observation. Three months later she had a normal menstrual period, followed by amenorrhea lasting three months. A bearing-down feeling with metrorrhagia ensued, but there were no uterine pains. Flowing had continued intermittently. The uterus was enlarged and solid tumors were felt on the anterior wall toward the right and also on the posterior. In the region of the left horn there was a tender and soft tumor. Violet coloring of the vaginal mucosa was marked. The uterus was curretted and some old clots with a substance resembling decidua were removed. The abdomen was opened and a large organ studded with fibroids and the tender uterine horn was visible. At a point beginning just inside the left tube for a small area the uterine wall was thinned out so that it was covered only by peritoneum. An incision was made through the thin portion along the fundus and through this opening a three to four months fetus with cord and placenta were shelled out. The fetus had evidently been dead but a short time. With the finger a hole was made connecting with the uterine cavity. The fetal cavity was closed with buried catgut sutures, the peritoneum being brought together over the incision. Fibroids were then removed. Discharged on the eighteenth day.

New York Medical Journal, December 4, 1909.

The Influence of Diet on Infant Mortality.—J. P. Crozer Griffith's paper is a plea for a more careful preparation of the infant's food. He considers that the ferments, alexins, antibodies, and other substances are in many respects different from those in cow's milk. It is possibly through their influence that an infant can be made to thrive if only it is given daily one or two feedings from the breast. Something imbibed in this way appears to make the cow's milk more readily absorbable by the digestive tract. Many of the maternal excuses for early weaning are purely fanciful, and no woman should wean her child except under the physician's direction. Especial care should be taken to prevent in bad weather the decomposition of food which has been properly prepared. Clean milk, free from dirt, is the first necessity. In regard to Pasteurization and sterilization of milk the author says that prolonged heating at a high temperature destroys many of the natural ferments and likewise alters the digestibility of the proteins by its action on the lime salts. Many of the ferments and other bodies are not affected by Pasteurization at proper temperature. From a purely clinical standpoint there is no doubt that milk of poor quality is much more harmful raw than sterilized. He himself has little fear of the bad results attributed to heating as compared with the danger of milk rich in bacteria, and believes that with all doubtful milk, and probably with all milk during the hottest weather, Pasteurization is to be recommended. The sale of commercially sterilized and Pasteurized milk is to be condemned. It has been shown that Pasteurized milk will develop dangerous bacteria more rapidly than will raw milk, the heat having destroyed the lactic acid germs, which, if left alive, check by their growth the development of the proteolytic varieties. Pasteurized milk is, then, valuable, but the necessity of care in its production and especially the care of the product afterward, is evident. The term "sterilized milk" and "Pasteurized milk" on the milk wagon merely give the mother a false sense of security, even supposing that the process has been honestly and properly carried out by the dealer. All sterilization and Pasteurization should be done at home.

The Immunizing Treatment of Hay Fever.—Dr. W. Scheppegrell comments on the practical failure of the vaunted serum treatment. He believes that the exciting factor in the disease is not the golden rod, but the rag weed. This plant has certain histological peculiarities which make it unusually likely to scatter its pollen throughout the air. This plant is not, however, responsible for all cases. The upper air tract should be put in a condition of anatomical integrity. This alone will cure 15 per cent. of the cases. The pollen of rag weed contains a pungent, aromatic compound which is irritating to the nasal mucosa. The author uses the pollen of the staminate flowers for inhalation by the patient. These inhalations are followed by mild typical symptoms. The preferable time for the inhalations is just before the usual time for the appearance of the patient's annual attack. Gradually the inhalations cause less and less reaction and the patient becomes immune for the time, but the treatment must be continued throughout the entire hay fever season of each year. There is no need to keep a patient within doors. He should by all means take his usual outdoor exercise, but be very careful to avoid rich and indigestible foods. To secure the pollen for use the author advises the wrapping of a couple of teaspoonfuls of the staminate flowers in a gauze bag and then tapping or rubbing this before the nares. Such a device can be used some ten times before losing its strength. It is better to use fresh flowers, but the author has found effectiveness in flowers two years old. They must be gathered before the first frost, for this disintegrates the pollen and destroys its effectiveness for the purpose desired.

Typhoid Fever from the Surgical Point of View.—A. E. Isaacs speaks of the various surgical aspects a typhoid case may assume in addition to the perforation of the bowel. We may have gangrene with sepsis, furunculosis, cellulitis, and erysipelas, fecal fistula, etc. Another and more serious class of suppurations that are likely to occur during the course of the disease is involvement of the internal organs and, unlike the superficial lesions, the source of the infection is from within, and may be carried to its place of lodgment in various ways, which will be considered under four headings: (1) By transportation by the blood current; (2) by extension through the lymphatic circulation; (3) by direct continuity, or by extension from one organ to another along the caliber of connecting tubes or ducts; and, (4) by changes in the blood and vessel walls permitting clotting and thrombosis, and parenchymatous changes in the organs, all due to the disorganizing effect of the toxemia on the cellular elements. Cholecystitis is a complication which calls for special mention, as it seems to take on a very virulent course in typhoid. It may occur in the third week or later. Gangrene and perforation may occur. Even with operation it has a mortality of 50 per cent. Without it the condition is fatal. Intestinal perforation is a comparatively frequent and most serious complication, and is the result of the intestinal ulcerations peculiar to the disease. It is most likely to happen in the third or fourth week, though it may occur earlier or later, especially in a relapse. It takes place, according to Harte and Ashhurst, in about 2.5 per cent. of cases, this figure being based on a total of nearly 3,000. According to the same authors the perforation is single in 85 per cent., and the location is in the ileum within 12 inches of the ileocecal juncture in 75 per cent., and over three feet away in only 2 per cent. of cases. At the Beth Israel Hospital for the three years to September 30, 1909, among a total of 217 typhoids, there were eight perforations, a proportion of 3.5 per cent., half again as high as the figures quoted. The most important element in the prognosis is the timeliness of the operation. If done within from six to eighteen hours of the time of perforation there is a reasonable hope for success. If the condition is unrecognized or neglected until the resulting peritonitis gains sufficient headway to add an additional septicemic element to the existing septicemia infection of the disease, the prognosis is necessarily influenced in proportion. Yet hopeless looking cases are so often successful that every patient ought to be given the benefit of the chance, be it ever so small, of relief by operation. Of the eight patients at the Beth Israel Hospital during the period stated, one died without operation, seven were operated upon, of whom five died, a mortality of 72 per cent.

Journal of the American Medical Association, December 4, 1909.

Occupations and Disease.—D. L. Edsall notes the inexactness of case records in regard to the antecedents and occupations of the patients. Mere general terms are too often employed. The occupation is put down simply as laborer, mechanic, etc. It would be folly, he thinks, for us to carry in our minds the details of all occupations and this is especially shown in the occupations predisposing to plumbism. Years ago Layet collected one hundred occupations in which there was danger of lead poisoning, the Edsall has been able to add considerably to this list. We can, however, he says, adopt some system of attempting to elicit the main facts and follow up particularly suggestive admissions. As an illustration of the details that may be brought out, he mentions the excessive liability of carriage painters over other painters to lead poisoning, and the fact mentioned to him by one of the Pennsylvania railroad surgeons, of the liability of locomotive engineers to the right-sided sciatica, caused by their sitting in a sideway position on the right-hand side of the cab in the springless locomotive. There are many important effects of heat also which have not been generally recognized on account of the too exclusive attention to heat-stroke and heat-prostration; there are many local effects also of strain occurring in special occupations and the same is true of the causes of heart affections and mercury poisoning, which is especially accompanied by nervousness and apprehensiveness. We have learned also, through a study of occupations, many other curious effects of poisons, as shown strikingly in the preference of lead to attack the upper extremities, and that of arsenic to attack the lower limbs, of methyl alcohol to attack almost alone the optic nerve. On the other hand we have striking evidence that serious neurotic states may follow on purely nervous and chiefly psychic influences—evidence furnished by telephone operators, for example, whose work is so full of strain that Wernicke said that every one of them who continues work for several years becomes hysterical. This is probably an extreme statement, but others who have studied the question agree that hysteria and neurasthenia are unduly common among such workers. There is an opportunity here also to advance our knowledge of cancer and we know already some facts on this point, among which he mentions the unusual amount of cancer among agricultural workers. The sociological and political bearings of the question are also noted and Edsall points out how legislation in regard to the prevention of disease may need to be varied in different countries. Thus in this country where certain

unhealthy occupations, such as matchmaking, etc., are carried on by large corporations and mainly by machinery where the operators are little exposed, are very different from those in Germany, where such work is still largely done in little home factories. The concentration of capital in this country has therefore in this, as in many other ways, made our conditions here superior to those abroad. He visited, for example, a certain paint factory and found that only one man was at all seriously exposed to lead among all the workers.

Cancer of the Uterus.—H. J. Boldt speaks of the necessity of an early diagnosis of uterine cancer and says that the palliative treatment of inoperable cancer becomes all the more important when we recall that by preventing the nutrition of the cancer cells we cause them to undergo retrograde metamorphosis and thus destroy their activity. It has been asserted by some that cancers can be cured in this way. The late Lawson Tait asserted that he had seen some spontaneous cures of cancer, and Boldt here gives some personal observations of his own which would appear to support this statement. It seems evident that small cancer remnants can be disposed of by the system. But he does not believe in radical surgery in such advanced cases as are usually called inoperable. He prefers to do a palliative operation with curette and cautery, and believes the results are just as satisfactory as to the longevity of the patient and far better as regards immediate mortality, for the curette and cautery operation should cause no deaths directly unless from the anesthetic. If the neoplasm, however, has progressed toward the bladder or the vagina, and is extensively infiltrated, it is inadvisable to use the cautery. He figures and describes a specially heavy curette and speculum surrounded by cold water devised by him to prevent burning of the vagina in these cases. Pieces of ice or ice shavings can be employed to cool off the cavity which is being charred and, with the cooling speculum, burns are entirely obviated. After the eschar has been thrown off it is well to use strong tincture of iodine in the cavity every second day until it is contracted. He thinks that acetone might be even better. He knows of no treatment which will control bleeding and offensive discharge so satisfactorily as will excavation and cautery. Other agents and methods are mentioned such as the chloride of zinc, pyoktanin, and carbide of calcium. The acetone treatment, recommended by Gellhorn of St. Louis, seems to be of value after cauterization has been completed. We can not always be certain of the nonexistence of cancer remnants in apparently cured cases, and this will explain recurrences after many years. In other cases of apparent cures we may question possibly the diagnosis.

The Palliative Treatment of Uterine Cancer.—W. B. Chase holds that the early radical measures have about reached their limit in the treatment of uterine cancer and that the palliative treatment is not receiving the attention it deserves. His statements have more reference to cancer of the cervix than cancer of the body, but the same principle applies to both. When the disease has reached the adjacent structures it may be advisable to limit the treatment to the superficial area of ulceration. After long personal observation and experience he is convinced that no palliative treatment is so effective as the thermocautery, which has the advantage of thoroughly closing the lymphatic vessels. Whether its superiority over caustics is due to the influence of heat on the diseased cells beyond the area of cell destruction is a matter of opinion, but he is inclined to think it probable. He specially emphasizes the fact that it is rare for the patient to suffer pain after the use of the thermocautery if the mucocutaneous surfaces are not injured. This requires tact and experience. He has usually found it easiest to protect the surfaces from injury by the use of strips of asbestos paper of proper size and shape. He alludes to Dr. John Byrne's method of the use of the galvanocautery, which he calls the correct one, and which consists in the gradual eating out of the diseased tissue of the uterus nearly to its peritoneal covering by the use of a platinum wire loop for the cautery and curetting away the burned tissue. Skill with this method consists in not going far beyond the area of involvement and having the cautery just hot enough to burn the structures but not to disintegrate them too rapidly. If proper heat is not maintained troublesome hemorrhage may follow. He has seen patients with cancer, far advanced, of the cervix and body showing signs of grave systemic infection, who lost their cachectic appearance after thermocautery operation. The greatest gentleness should be employed in all manipulation of the parts after operation and a bivalve speculum should not be used as a rule, as it is likely to infringe on the burnt area. Daily vaginal douches with permanganate of potassium or compound solution of cresol are the best antiseptics. In hopeless cases this local treatment of galvanocautery is essential for the patient's comfort, and the skilled hand of the attending physician is the most satisfactory in applying the dressing. The local use of cocaine, frequently repeated, is sometimes useful in relieving pain, or rectal suppositories of cocaine and hyoscyamus are advisable. Later, increasing doses of morphine may be used. He has not been so fortunate as Dr. Byrne in thus preventing the local recurrence of the disease, which may be due, he says, to his less skillful technique. There is no reason why in recurrent cases of thermocautery cannot be repeatedly used with benefit. He gives the history of four patients, two of whom after periods of from four to eight years, according to accepted standards, were cured, and the other two were greatly benefited and their lives prolonged for years with very little suffering—a result unobtainable, so far as he knows, by any other treatment. His experience with *x*-ray and radium treatment has not been sufficiently extensive to enable him to speak authoritatively as to their value, but, as far as his experience goes, he regards radium as far the more useful, since after its use granulating surfaces take on a more healthful activity than after the use of the *x*-ray.

Magnesium Sulphate Anesthesia.—S. Solis Cohen has noticed that the external applications of magnesium sulphate solution relieved certain deep-seated pains of arthritis, cutaneous inflammation, etc., he would not say in consequence of, but sequent to the application. In order to test whether or not this was a psychic phenomenon, other applications were made—simple saline solution, distilled water, magnesium chloride, sodium sulphate, etc. While any moist dressing alleviated the pain somewhat, none of them had the decided effect of magnesium sulphate. To determine whether or not any local anesthesia was produced, the tactile sense, pain sense, and thermal sense were tested in normal persons, in the patients relieved by magnesium sulphate, and in the patients not relieved by it. In no instance was any effect of any kind on the cutaneous sensations detected, whether the examinations were made within ten minutes or after from thirty minutes to an hour. He represents this merely as a curiosity of observation, but thinks it may be useful at times when one does not care to give morphine for deep-seated pains. The problem is complicated and the method of observation is inexact, so that he cannot say that there really was a positive action of magnesium sulphate in these cases. He deems the matter, however, worthy of further observation.

Vasectomy.—H. C. Sharp quotes the statistics of Indiana for the last eighteen years as evidence that it is race degeneration and not race suicide that should cause us to be apprehensive of the future. Certain States have passed laws for the purpose of restricting the marriage of degenerates, but the tendency of such laws is to restrict propagation only in the more moral and intelligent classes and to have no effect on the more dangerous degenerates. He therefore pleads for the defertilization of degenerates and says that since October, 1899, he has been performing an operation known as vasectomy, which consists of ligating and resecting a small portion of the vas deferens, which can be done in three minutes without an anesthetic and without interrupting the normal activities of the individual. He has had 456 cases, affording splendid opportunity for observation, and has seen no bad effects, though effectively sterilizing the individual. On the other hand it seems to improve the disposition and to increase the muscular power. He reports that he has had good results in cases of neurasthenia from this operation. It diverts the function of the sexual glands to their internal secretion. He describes his operation and says that it is being carried out effectively in the Indiana State Reformatory, and it is to be regretted, he thinks, that it is not also performed in the other State institutions.

The Lancet, November 27, 1909.

Some Complications and Dangers of Nasal Surgery.—H. B. Tawse refers to the great advances which have taken place in nasal surgery during the last two decades,

and points out some of the complications and dangers which, in view of the present extensive operations undertaken, were unknown years ago. He refers particularly to the middle turbinate bone and speaks at some length about its polypoid degeneration. This, with the frequent concomitant sinus suppuration and the evisceration of the ethmoid region, call for special carefulness. The special complications are hemorrhagic effusion into the eyelids and orbits, orbital abscess, necrosis of the frontal bone, necrosis of the superior maxilla, fracture, puncture and laceration of the cribriform plate, suppurative meningitis apart from injury, severe hemorrhage, and optic neuritis and blindness. The effusion into the eyelids, etc., is very common and of no threatening moment. In cases of polyps in old people with long standing sinus disease, the turbinal tissues are of a pale blue anemic color and the seat of extensive degeneration. The bone destruction is usually much greater than can be determined by speculum and probe. In cases of suppuration of the frontal sinus, it must be remembered that we are working separated from the brain by only a thin plate of bone, and that while fatal results are comparatively rare they are by no means unknown. Free drainage is the great desideratum. If the case goes on to an osteomyelitis a fatal result is inevitable. We should not be too zealous in those cases in which the pus escapes freely from the sinus and which show no impairment of the general health. Moreover, after some of these operations a long course of after-treatment is necessary, and we must be sure that the patient's confidence will stand this. Postoperative neuroses are quite common after these serious intranasal operations.

Severe Case of Exophthalmic Goiter in Which Treatment by the X-Rays and Sour Milk Appeared to Be Beneficial.—J. C. Newman's patient was a single woman of 31 years who presented the typical appearance of a case of Graves' disease. The most painful symptom was vomiting, of which she had several obstinate attacks. Various remedies were tried with reference to the relief of this symptom and to the cure of the general condition. None were of any aid, however, and the patient became nearly moribund, so greatly was she reduced. *X*-ray seances were given, each lasting about seven minutes, the sides of the thyroid being treated alternately at each sitting and the latter being repeated twice weekly. This treatment appeared to be beneficial. During the wasting the thyroid gland had shared in the process, but as the patient began to mend, it resumed its former size. Another attack of vomiting was followed by wasting, but as the patient recovered the gland did not enlarge again. The stomach again becoming upset, she was placed on milk soured by the lactic acid bacillus, and from this time she began to have relief from an obstinate diarrhea of some duration. At this time the diet consisted of little but milk, and her stomach was dilated and probably in a condition of atony. Under the conditions named her intestines may have received little else than sour milk and this after they had been pretty thoroughly flushed out. The conclusion that her improvement was due to the exclusion of intestinal toxins assisted by the reduction of activity of the thyroid gland under *x*-ray treatment seems to the author a legitimate one.

The Relation of Alcohol to Immunity.—F. R. Parkinson says, (1) That alcohol in small quantities has no action of phagocytic activity; (2) it has no action of phagocytic activity until it is present in 12.5 per cent. strength; (3) small quantities injected into rabitts may temporarily stimulate the production of antibodies; (4) a large dose of alcohol lowers the opsonic index for 24 hours; (5) continuous moderate doses cause a permanent lowering of the opsonic index; (6) the reacting mechanism to vaccines is much less effective in alcoholized rabbits than in normal rabbits. The difference is still more marked when living microorganisms are used.

Comparison Between the Antiseptic and Aseptic Methods of Operation, with Special Reference to the Occurrence of Suppuration.—H. S. Pendlebury and Ivor Back present a study of this question based upon the results obtained at St. George's Hospital during the years 1906 and 1908, respectively. They describe certain plans used at the institution in establishing the aseptic régime and give their comparisons based on the two methods in tabulated form, which cannot be reproduced here. In operations for hernia the septic percentage was lowered from 13.8 to 9.6 per cent.; in breast cases it rose from 8.7 to 12.2; on thyroid gland reduced from 7.7 to 6.2; in operations on the male genitals reduced from 14.3 to 6.5; in quiescent appendicitis reduced from 9.2 to 3.3 in all cases of appendicitis reduced from 13.5 to 9.4.

British Medical Journal, November 27, 1909.

Two Rapidly Fatal Cases of Pneumonia.—Cases are reported by W. T. Mills. The first was that of a man who was seen in public by the author at six o'clock one evening. He was called about two hours later, and found pneumonia at the left base. The man was gasping for breath, and could not lie down. In spite of injections of strychnine and digitalis and other remedial measures, he died in six hours. The other case was that of a farmer of 31 years, weighing over 230 pounds. Two days before he had been wet through. The next day he worked in a draft and the author was called to see him in the evening. A small patch of congestion was found at the base of the right lung and a diagnosis of pneumonia was made. The next morning the condition was more pronounced and he died in 35 hours. His face became quite black before death, and immediately after death blood flowed from the mouth. There was such a layer of fat over his body that no veins were visible in the arms, even after applying a tourniquet, for the author was prepared to bleed him if the blood would flow. The temporal artery was not opened, as it was considered that this procedure would not relieve the right side of the heart. Hypodermics of strychnine were given in this case also, but without avail.

Auricular Fibrillation; a Common Clinical Condition. T. Lewis says that it is well known that in late stages of mitral stenosis and in cases of general cardiovascular degeneration the pulse is frequently continuously and extremely irregular. It has been supposed that the rhythm of the heart producing it has had its origin in the node of Tawara. Facts at the author's disposal permit of the following conclusions: (1) That a rhythm arising in the neighborhood of this node occasions a totally different clinical picture. This conclusion is based upon a detailed examination, by recording apparatus, of a case of paroxysmal tachycardia in which it can be demonstrated that the auricle and ventricle contract together. (2) That the irregular pulse of mitral stenosis is due to fibrillation of the auricle. (*a*) The clinical irregularity presented by arterial and heart apex curves is unique. The rhythm is entirely disorderly and the sizes of the beats do not correspond to the pauses which precede them. Fibrillation of the auricle results in a similar action of the ventricle. (*b*) Electrocardiograms taken from patients exhibiting the irregularity show a number of irregular waves apart from the ventricular curves. They are found in no other disorder of the heart's action. They disappear when in a paroxysmal case the irregularity vanishes, and are therefore due to a temporary and disorderly action of some part of the heart wall. Cardiographic curves give no evidence of such a disordered action in the ventricle. Fibrillation of the auricle gives curves which are identical in every respect, and no such curves have been obtained by experimental means. Further, the waves on the experimental cardiograms can be shown to correspond to the fibrillary movements in the auricle by means of synchronous tracings. (*c*) The venous curves in the clinical irregularity are of the ventricular type. All the prominent curves occur during the ventricular systole, and there is no wave corresponding to a normal auricular contraction. The same statement applies to the venous curves in fibrillation of the auricle.

A Case of "Giant Feet."—The case is reported by H. Stevenson, whose patient is a boy of four years, apparently normal at birth, with the exception of toe deformity and some enlargement of the ball of the left foot. At the age of six months, when vaccinated, lumps appeared in the leg and groin. Gradually the enlargement spread upwards toward the axillæ and at the same time the arms grew thinner. At the present time the two inner toes of the right foot are normal in development. The three outer toes are very much enlarged and resemble small tubers. They are acutely dorsiflexed, and arise from a much thickened sole pad. The left foot is even more deformed, only the inner toe escaping and the characteristics described on the right side are more exaggerated. The left leg, thigh, groin and infrascapular regions are sites of large, fatty tumors, and there is also a large one on the right buttock. When the child stands there is well-marked lordosis, due apparently to the weight of the tumor in the groin, and possibly to some intraabdominal growths. The child is nevertheless able to run about and to indulge in the usual sports of childhood. The skin is everywhere normal in appearance, and a section from one of the tumors has the appearance of an ordinary lipoma

Berliner klinische Wochenschrift, November 15, 1909.

The Prophylaxis of Tuberculosis.—Czerny says that the most important point in the prophylaxis of tuberculosis is to teach the laity that it is contagious from man to

man. For this reason it is of the greatest importance that each patient with tuberculosis should be informed of the nature of his disease. The author attempts in every case of tuberculosis among children to determine the mode of infection, in order that repeated infections may be prevented. In many cases the infection is obtained from persons who were not aware that they had the disease. The necessity of frankness in diagnosis and statement is especially strong, as we know that it is a curable disease. The tuberculosis infection often masks itself under the guise of scrofula. People do not appreciate that gland and bone tuberculosis may be a source of consumption. While it is customary to examine every wet nurse for tuberculosis before hiring her, it must be remembered that children not nursing may also contract the disease by being tended and carried by infected nurses. He knows many cases of children from tuberculosis-free families who had caught the disease from nursemaids. The general oversight of a family to prevent the spread of tuberculosis, formerly possible as a function of the family physician, is becoming more difficult, as he is being replaced by the specialist.

Wassermann Reaction in Milk.—Oluf. Thomsen has made a study of the Wassermann reaction as produced by women's milk in a series of cases, and says that the milk of syphilitic women very often gives a positive Wassermann reaction, and this reaction, which is usually strong, occurs not infrequently in women in whose blood serum a positive reaction cannot be obtained. The reaction appears, apparently, with unchanged strength during the first two or three days of lactation; then, if the mother nurses, it suddenly diminishes and usually has disappeared within five to six days of the birth of the child. If the mother does not nurse, the reaction remains positive and unchanged in intensity for at least from 8 to 14 days, after which time it is usually impossible to obtain specimens for examination. During the last days of pregnancy the reaction is similar to that of the first days of the puerperium. The milk of nonsyphilitic women can also, though rarely, give a positive reaction during the first days of the puerperium, but this reaction is far weaker than in syphilitic women. What value a positive Wassermann reaction in the milk may have in diagnosis and prognosis is not proved by the present investigation, as more material is required for such conclusions. Positive reaction, however, occurred when using less than 0.1 c.c. of "serum" only in the presence of syphilis. Hypothetically there is an inference of the relation of the local Wassermann reaction, in the milk and cerebrospinal fluid to the generalized reaction, in the blood.

Münchener medizinische Wochenschrift, November 16, 1909.

Intravenous Anesthesia with Ether and Chloroform.—Burkhart, who recently published a paper advocating the intravenous injection of chloroform for general narcosis, reports his results with the use of ether intravenously in thirty-three cases and of a mixture of ether and chloroform in eight more. He first experimented with a 10 per cent. solution of ether in salt solution on animals, but found that this caused too deep narcosis and severe hemoglobinuria. A 5 per cent. solution, on the other hand, caused no untoward symptoms. This strength he therefore used on men. Careful asepsis was carried out; 50 c.c. of ether was added to a liter of saline and shaken until completely dissolved. The vein was laid bare and the distal end ligated. The solution was injected steadily until anesthesia was complete, then stopped until the patient began to show signs of coming out, when more was given, usually from 30 to 70 c.c. at a time. Patients of all ages were used. In 29 of the cases the reflexes were absent during the entire period of anesthesia; in 4 they were present during at least a part of the time. A previous injection of scopolamin-morphine is recommended. The amount of ether required to produce narcosis varied greatly; one 4½-year-old child required 85 c.c. of the solution; children under 15 usually took 200 to 250 c.c.; the largest amount required was 380 c.c. In women it varied from 200 to 600 c.c., and averaged 320 c.c. In men it varied from 200 to 800 c.c., and averaged 600 c.c. The narcosis came on as a rule in from 8 to 10 minutes. In no case was any alteration in the breathing noted; it remained slow and quiet. Cyanosis was not seen. Râles were heard in only a very few cases. Noticeable variations in the rate and quality of the pulse were not observed; the infusion seemed to improve it. Vomiting did not occur. After effects, as vomiting, headache, and nausea, were absent in thirty of the cases. In no case was any pathological urine finding seen; there was neither albuminuria nor hemoglobinuria. There were no thromboses or emboli. In only two instances did there occur a bronchitis. The ether-chloroform narcosis was carried out by attaching two tubes to the cannula, one to a 5 per cent. ether solution and the other to 0.5 per cent. chloroform. In these eight cases, too, there were no bad symptoms, except in the cases where 0.7 per cent. chloroform instead of 0.5 per cent. was used. In these there was a transient hemoglobinuria. The author concludes that intravenous ether narcoses, combined with scopolamin, at least among adults, is the least dangerous and most convenient of all general anesthetics. It will, however, be reserved for special cases. It is indicated only in such cases and under such conditions that the asepsis is sure. Under these conditions it is indicated (1) in patients with imperfect respiratory and circulatory organs, in the weakened and debilitated, for in the absence of the primary stimulation to the respiratory organs and the reflex insult to breathing and heart the blood pressure is not altered, and overdosage is scarcely possible; (2) in operations on the head and neck as convenient to the operator; (3) with patients who have an idiosyncrasy or severe personal objection to the inhalation of a narcotic.

Treatment of Fracture of Thigh in the Newborn.—Zancarini discusses the various methods of treating birth fractures of the thigh. He has obtained his best results from using the infant's body as a splint. The fractured thigh is flexed over the abdomen and thorax and the foot put over the shoulder by the side of the neck, and the clavicle acts to hold it in position. The limb is bound in position by a simple binder around the body, the chest having been padded with cotton. The bandage is removed daily to allow of massage. This position is a reversion to the fetal posture, and causes the child no pain. The deformity of the thigh is overcome, and the length of the limb is maintained. The method may be applied by any physician, and is not objected to by the family. Three cases are reported.

Deutsche medizinische Wochenschrift, November 18, 1909.

Nephritis and Inflammation of Parenchymatous Organs.—Ribbert concludes an article on this subject by saying that the inflammations of all parenchymatous organs are confined entirely to the interstitial connective tissue. There is no parenchymatous inflammation, for the parenchyma of the especial organ takes no part in the process; it shows degenerative changes only. The parenchyma is not an active participant in the inflammation, which does not attack the entire organ, but merely has its seat in it. The retrogressive changes of the parenchyma are, however, alone responsible for the symptoms. The original inflammation (interstitial) has either no action in causing sickness, or else only indirectly, in that it damages further the previously uninjured tissue.

Glycosuria in Women.—Henkel discusses the greater prevalence of diabetes among men than among women, and reports two cases of glycosuria occurring as the result of pelvic tumors. The lesson which he draws is that tumors in the female genital organs may cause glycosuria, which disappears immediately upon excision of the tumors. As the operative prognosis in true cases of diabetes is notoriously bad, it is desirable to recognize these cases of "intoxication diabetes," for in them all treatment and temporizing is without avail and wrong, since with the excision of the tumor the sugar disappears from the urine. Clinically of diagnostic value are the facts that in these cases the sugar content is small, the urine is not especially increased in quantity, and the great thirst is absent. Not much weight should be put upon the presence of acetone and diacetic acid, as these may be found in other pure gynecological conditions without diabetes.

Hebosteotomy and Extraperitoneal Cesarean Section.—Baisch says that the dangers of the operation of hebosteotomy, namely, sepsis, hemorrhage, and injury to the bladder, may be overcome by proper technique and careful attention to the indications for operation. Hebosteotomy is contraindicated when the woman is unquestionably infected. The best preventive to injury of the bladder is Döderlein's method. Hebosteotomy is to be advised against with a pelvis of less than 7 cm. conjugata vera (6½ cm. with a small child) and in primipara with infantile genitalia. For such cases the extraperitoneal cesarean section is the best and most fruitful operation. After the sawing of the pelvic bones, spontaneous delivery is not to be awaited invariably. With multipara with wide cervix there is usually no objection to an immediate delivery. Hebosteotomy must not be preceded by an effort at high forceps extraction or by a version. Hebosteotomy and extraperitoneal cesarean section are indicated in all the cases of noninfected women, when spontaneous delivery cannot be expected. Spontaneous births, widening of the pelvis, and cesarean section are taking the place of high forceps, prophylactic versions, and *accouchement forcé.*

Book Reviews.

Expansion of Races. By Charles Edward Woodruff, A.M., M.D., Member of the American Association for the Advancement of Science; Fellow of the Medical Association of the Greater City of New York; Member of the American Academy of Ophthalmology; Author of "The Effects of Tropical Light on White Men," and of "The Evolution of the Small Brain of Civilized Man." New York: Rebman Company, 1909.

This is a book to which it is impossible to do justice in the limits of a necessarily brief review, for there is hardly one of its 500 pages which does not contain some statement to arrest the attention of the reader. Whether he agrees with the author or the reverse, he can but admit the cogency of the reasoning and confess that here is a book worthy of serious study, written by a man who knows what he wants to say and who says it in a way that admits of no doubt of his meaning. That it will arouse antagonism is certain; that it will make converts is most probable; that it will be proved wrong remains to be seen. It is a book that will bring comfort to the pessimist and to the optimist, but whether it will inspire the man who is neither, but who is filled with a burning desire to uplift the race, is questionable. The pessimist will say, "I told you so; it's no use fighting against Nature's laws; evolution proceeds along fixed lines, governed by inexorable laws, and all of little man's efforts here and there may help the individual, but have no effect in the long run." The optimist will say, "It's all right; the human race is working out its own salvation; wars and pestilences may come, the individual here and there may be given an opportunity for betterment or may be crushed in the struggle, but the race is marching on." The socialist and the man who wants to raise the little brown brother to a level with himself, at least to make him the ruler in his own land, will find little encouragement here; the earth, Major Woodruff believes, is the white man's, and if he cannot people it all—Nature opposing her barrier of the actinic rays—he must govern it. Moreover, Major Woodruff contends, as was said two thousand years ago, the poor will always be, for poverty is the inevitable result of inequality in mental and physical makeup.

The main argument of the book is the fluidity of population which flows away from congested centers to more open spaces, the term congestion or overpopulation referring not to the absolute number of individuals in a given area, but to the number of individuals in relation to the food-producing or food-procuring capacity of the country. When the population has reached the limit of its ability to get food, either the surplus must move on or the population will remain stationary. War and pestilence work no permanent change in population, for the gaps they cause are soon filled by an increased birth rate; when the balance is restored, the birth rate falls again. The normal birth rate is that which maintains the population at its limit, or an average of two children growing to manhood to each family, to fill the gap made by the death of the parents. All the factors entering into the growth and decay of nations—poverty and wealth, politics and governments, "race suicide," war, disease, socialism and individualism—are discussed in an illuminating way and so as to make clear many of the great problems of history.

There is an almost brutal frankness in this book which gives the reader many shocks, but he is forced to admit in the end that facts are facts. As the author says in his Preface: "Throughout it has been the object to describe merely the facts and the laws governing them. There is no right or wrong in natural phenomena, and therefore no attempt has been made to hide the awful brutality, suffering, poverty, and immorality which have been part and parcel of man's evolution. . . . The facts are stated, and if we are shocked we must remember that it is natural that most of us must be crowded out of existence before reaching the Biblical age of threescore and ten. Ethics never bothers Nature, and we are governed by natural laws to an extent we have never realized." In a word, the book, to quote again from the Preface, "merely applies to man the natural laws which are known to govern the spread of all other species of plant or animal. It then explains the relationship of higher and lower races of man, and shows why we expanded across the Atlantic to America in the sixteenth and seventeenth centuries, and thence across the Pacific, and why the higher races must always control the tropics, though acclimatization and colonization are not possible." There is a great deal about the Philippines and the problems which their acquisition presents to this country, and evidently the author does not believe that we can ever let them go. Any one who has recently been in the Philippines and has seen the tremendous, Gibraltar-like defences which we are constructing there will be inclined to believe that the author is right, and that this country never will and never can lay down "the white man's burden" which it has, fortunately or unfortunately, taken up on the other side of the Pacific.

This is a great book, and one that will broaden the view of the reader, whether it commands his approval or not. It will give him food for thought and will cause him to view even the every-day occurrences of life and the news of the morning with an interest born of their unsuspected relation to the great problem of human destiny.

L'Hypophyse et la Medication Hypophysaire. Etude Experimentale et Clinique. Par M. le Docteur Arthur Delille, Ancien Interne des Hôpitaux de Paris, Ancien Moniteur de Tubage et de Trachéotomie, Membre Adjoint de la Société Anatomique, Lauréat de la Faculté de Médecine de Lille. (Trois Médailles d'Argent et un Prix Spécial.) Médailles de Bronze de l'Assistance Publique, Médaille d'Honneur des Épidémies. Paris: G. Steinheil, Editeur, 1909.

In this treatise the author has gone into an exhaustive study regarding the secretion of the pituitary gland, investigating its chemical and toxic qualities as well as its physiological action on the heart and blood-vessels, kidneys, smooth or striated muscle fibers, etc. He also takes up the association of this extract and those of the thyroid, suprarenal gland, and ovary, and the effect of hypophysectomy and the use of the extract following the lines of the studies in myxedema. The last part of the pamphlet deals with the pituitary extract upon the healthy man and upon invalids and a study of the lesions found in this interesting gland in various diseases. On the whole, it makes interesting observations on a subject as yet little understood.

General Medicine. Volume VI of the Practical Medicine Series. Edited by Frank Billings, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago; and J. H. Salisbury, M.D., Professor of Medicine, Illinois Post-Graduate Medical School. Series 1909. Chicago: The Year Book Publishers.

This is the second volume of the "Practical Medicine Series, 1909," that has been devoted to the consideration of general medicine. Among the subjects considered in this book are some of the acute infections, such as typhoid fever, malaria, cholera, and dysentery, the diseases of the alimentary tract, liver, pancreas, and peritoneum. This, with the contents of Volume I, covers the year's progress in general medicine.

Studies in Tuberculosis. By Henry Clarke, M.A., M.D. (Cantab.), Physician to the Liverpool Hospital for Consumption and Diseases of the Chest; Superintendent of the Research Laboratory of the Hospital; Councilor of the City of Liverpool. Liverpool: At the University Press; London: Archibald Constable & Co., Ltd., 1909.

The present essay, comprising a series of studies, is an elaboration of the author's thesis submitted for the Cambridge degree of Doctor of Medicine. The author has divided his subject into three sections: Diagnosis of consumption, prevention of tuberculosis, and treatment of tuberculosis. In the section on diagnosis the author very properly emphasizes the importance of a careful inquiry into the history and antecedents of the patient. He has adopted a very convenient scheme for history taking. In his consideration of the physical examination he has wisely avoided any discussion of detail, referring the reader to the many authorities for a review of that phase of the subject. There is brief consideration of the specific reactions used in the diagnosis of tuberculosis, including the various tuberculin tests and the opsonic index.

Section two, on the prevention of tuberculosis, comprises some very pertinent suggestions as to municipal and State control of the disease, and particularly on the possibility of eradicating tuberculosis among cattle as a preliminary measure to lessening the incidence of the disease among human beings.

The section on treatment is devoted almost entirely to a consideration of specific treatment by means of tuberculin vaccines. The author briefly considers a few of the many preparations of tuberculin, and more fully discusses the various methods of administration. It is evident that he prefers the German to the English method of dosage and interval. The text of this section is rather freely illustrated with some interesting opsonic index charts and tables showing the results of specific treatment in forty consecutive cases. The author has appended a full bibliography covering the subject matter of his essay.

SECTION ON SURGERY.

Stated Meeting, Held November 5, 1909.

DR. ELSWORTH ELIOT, JR., IN THE CHAIR.

Blood Transfusion for Uncontrollable Bleeding in a Child with Hemophilia.—Dr. CHARLES GOODMAN presented this case. The patient was over two years old and was admitted to the Beth Israel Hospital twenty-four hours after having fallen on his face from a fire-escape to the landing below. There was a lacerated wound of the right cheek surrounded by a hematoma occupying the entire right side of the face, extending to the lower eyelid. The buccal mucous membrane was lacerated in several places, and the upper lip was completely severed. This had been sutured before his admission to the hospital. These wounds were oozing when he was brought to the hospital. The surface of the body was covered by ecchymotic spots. The child was very pale. During the first two days applications of adrenalin chloride, nitrate of silver, ice, and pressure with gauze pledgets were tried to check the bleeding; salts of calcium were also administered by mouth, saline solution was given by rectum, and saline hypodermoclysis and diphtheria antitoxin was given in two doses hypodermically, without result. Blood was vomited, and the child had several bloodstained movements. The transfusion of healthy blood was considered, and the mother volunteered to be the donor, but she was rejected because she was in her eighth month of pregnancy. A donor was finally obtained in a healthy young fellow, nineteen years old. At the time of transfusion the blood examination showed hemoglobin 12 per cent. and less than 1,000,000 erythrocytes. After ten minutes' transfusion there was gradual return of the pulse and beginning coloration of the lips and ears. The transfusion was continued for twenty-eight minutes; at the end of this time the pulse was regular, of good quality, and 140 in frequency. The ears, cheeks, and lips, previously waxy, had now become pink. The hemoglobin was 70 per cent. The child became restless and begged for nourishment. About an hour and a half after the transfusion there was a sudden rise of temperature to 106.4° F. and a pulse of 190. Without treatment the temperature and pulse subsided in twelve hours. An uneventful recovery followed. The points of interest noted were that the oozing from the wounds was not only interrupted by the transfusion, but absolutely checked by it. The ecchymotic spots which covered almost the entire body of the child gradually faded away, and no new spots reappeared. When discharged from the hospital eighteen days after admission he showed a red blood count of 3,400,000 and a hemoglobin percentage of 50. Three weeks later there were 5,000,000 erythrocytes, with a hemoglobin of 80 per cent. The diagnosis of hemophilia in this case was established by the history of obstinate bleeding following circumcision; extraordinary blood loss following trivial injuries; the tendency for the child to develop ecchymotic spots upon slightest contact with hard objects; the persistent oozing from the wounds and mucous membranes following the injuries which resisted almost every means of treatment.

Trephining for Perforating Wound of the Skull.—Dr. CHARLES GOODMAN presented a boy, nine years of age, who was struck on the head by a broken window frame which had fallen from the third floor. A diamond-shaped piece of glass struck the median line of the head at a point corresponding to the junction of the sagittal and coronal sutures. The house surgeon in attempting to remove the projecting piece of glass broke it off close to the skull. When Dr. Goodman saw him he could see the broken fragment of glass firmly wedged in the bone. With the trephine he removed a button of bone with the glass fragment. An examination of the specimen showed that the cranium was perforated, causing a depressed fracture of the inner table. The sharp spiculi of bone in the inner surface caused a very minute perforation of the superior longitudinal sinus. The bleeding was readily controlled. The specimen was rather unique: had he made use of any other method for its removal it would have probably resulted in a serious laceration of the sinus.

Dr. WILLIAM A. DOWNES reported the case of a girl, two years and eleven months of age, who had no history of tuberculosis, neoplasm, lues, nor hemophilia on either side of the family. There was one child older and one younger, neither of whom had shown the slightest tendency to bleed easily. When two years old it was noticed that the slightest bruise left an area of discoloration. She had nose bleeds, beginning sometimes when sleeping. Four months before seen she fell and received a lacerated wound of the scalp, which was sutured; that night the wound bled freely, and the hemorrhage was controlled only by deep sutures. The entire upper part of the face around the eyes became discolored. She had several severe attacks of epistaxis, which were controlled only after the loss of a large amount of blood. This patient was admitted to the House of Relief August 5 with epistaxis and weakness. On August 8 the blood count showed red cells, 2,300,000; white cells, 18,200; polynuclears, 44 per cent.; small mononuclears, 40 per cent.; transitional and large mononuclears; hemoglobin, 30 per cent. On August 12 the patient was given 100 c.c. of artificial serum; this was followed by a severe chill and a temperature of 105.2°. The epistaxis, however, was checked. On August 14 the red cell count was 2,180,000, the white cell count was 16,500; the polynuclears, 26 per cent.; small mononuclears, 71 per cent.; transitionals, 2 per cent.; large mononuclears, 1 per cent.; hemoglobin, 25 per cent. There was no more epistaxis. The temperature ranged between 98° and 100°. The examination of the urine was negative. The patient was then transferred to the New York Hospital and then to the White Plains Convalescent Home. On October 2 she was brought back because of persistent epistaxis. The nares were packed with gauze saturated with adrenalin solution, but the bleeding was not controlled. On October 4 she was infused with 200 c.c. of artificial serum, and there was no further bleeding for thirty-two hours, when the bleeding again appeared, and it was thought that she would die in consequence. On October 5 a transfusion was made from the father as the donor. This was continued for fifty-five minutes. The child was then rosy and warm, the lips were red, the pulse 160 and of good quality. There was a slight epistaxis of dark red blood, which soon ceased. The hemoglobin percentage, taken every ten minutes, showed a steady rise from 14 per cent. to 68 per cent. The recovery of the patient was uneventful, and she was discharged on October 29 with a hemoglobin percentage of 89.

Isolated Dislocation of the Head of the Radius.—Dr. EUGENE HILLHOUSE POOL presented a boy who, seven weeks previous to admission, fell from the top of a range. For four weeks the arm hung at the side in the extended position. The awkwardness of his movements and the deformity caused the parents to seek medical advice. Examination showed the upper part of the left forearm to be much broader than the right. With the elbow extended, the outer margin of the left forearm just below the elbow showed a marked rounded swelling, the most prominent part corresponding to the site of the head of the radius. There was complete absence of carrying angle. Flexion was invariably accompanied by pronation

of the forearm, during which the elbow was abducted. Full pronation was possible, but supination was limited. The identity of the head of the radius was fully established by its rotation with the shaft of the radius in pronation and supination. The bony prominence was quite freely movable in an anteroposterior plane and also outwardly to a considerable extent. The shaft of the ulna and prominences of the elbow were normal. The displacement was readily corrected by placing the supinated forearm in full extension and adducting the forearm, at the same time directing inward pressure upon the head of the radius. To prevent recurrence of the dislocation, the most favorable position seemed to be extension and supination. All the movements of the arm were now normal. Outward dislocation of the head of the radius, the most infrequent, was usually associated with fracture of the ulna or radius. Of outward dislocations without fracture, there were very few recorded cases.

Extirpation of a Pharyngoesophageal Pressure Diverticulum.—Dr. De Witt Stetten presented a case which illustrated two important points, that not every spontaneous, organic esophageal stenosis, developing after middle life, was due to carcinoma, and that proper radiographic studies were positively indispensable in the diagnosis of disease of the esophagus. The patient was a man, sixty-eight years old, whose illness began over two years ago, when he noticed a gradually increasing difficulty in deglutition without pain, but with occasional regurgitation, and attacks of coughing and choking. The esophageal bougie was obstructed at about 16-19 cm. from the teeth. After considerable manipulation he finally was able to enter the stomach with a No. 32 Fr. At the second examination one week later the stenosis seemed to be tighter. A diagnosis of carcinoma of the esophagus at a not infrequent site was made; this diagnosis was agreed to by other surgeons, and a Witzel operation was performed, from which the patient made an uneventful recovery. During the following sixteen months the course of the disease was most gratifying and surprising. He gained eight pounds in weight, and had been able to partake of his regular meals. There was some improvement in his ability to swallow solids, while liquids had gradually been causing him more difficulty. A cough after eating and on lying down at night had been particularly annoying. He never succeeded in passing a larger number than 23 Fr. after the operation. There was no tumor in the neck. It was evident that the original diagnosis was incorrect, and the *x*-ray was used. One plate showed an accumulation of bismuth paste in a dilated esophagus above a stricture located at the level of the seventh cervical vertebra. A second plate gave an anteroposterior view and showed a perfectly circular accumulation of bismuth just above the suprasternal notch, slightly to the left of the median line. It was undoubtedly a typical pharyngoesophageal pressure diverticulum which, by compression and deviation of the gullet, had produced the stenosis. After a thorough course of oral hygiene and the exclusive use of the gastrostomy for feeding purposes for five days, it was felt that the upper part of the alimentary tract was in as aseptic a state as it was possible to procure, and a radical extirpation of the diverticulum was performed. His convalescence was uneventful. The wound healed primarily. On the eleventh day after the operation a No. 36 Fr. bougie was passed with ease, and the gastrostomy tube was removed. The gastric fistula closed spontaneously. The specimen was a small rounded sac about the size of a walnut and was lined with mucous membrane. The walls consisted mainly of a thickened, fibrous submucosa covered in parts with strands of muscular tissue. He believed that the preliminary gastrostomy reduced the risk of the operation. It permitted of preliminary emptying, resting, and cleansing the sac, of operating in a comparative aseptic field, and of subsequent feeding, answering very much the same purpose that a colostomy did in an excision of the rectum, and eliminating the danger of the operation, periesophageal phlegmon and posterior mediastinitis.

Intrathoracic Resection of Esophagus, with Esophagogastrostomy.—Dr. Willy Meyer presented this paper. He said that with the apparatus at hand to-day the esophagus could be safely attacked by the surgeon in its thoracic portion. In attacking cancer of the esophagus there were three methods. (1) Extirpate the growth, close both ends, and establish a gastric fistula. This meant that the patient should be fed through life with a stomach tube unless a second operation was performed, reestablishing direct communication between proximal end of the esophagus and the intestinal canal. (2) Open the thorax, and pull the stomach into the thoracic cavity, excise the growth, and do an esophgogastrostomy. This was the ideal method, for it enabled the patient to eat and drink. (3) Esophagojejunostomy. This method should be employed in those cases where the growth was situated so high that it was impossible to pull the stomach up sufficiently for direct anastomosis. Among the causes for the unsatisfactory results in this kind of work had been the fact that there was an absence of pleural covering of the lower third of the esophagus; there was also the lack of a useful method. Dr. Meyer said that he had worked out a method at the Rockefeller Institute for Medical Research during the course of last winter. The operation was done with needle and thread. For this operation on dogs he had substituted artificial means for anastomosis, as, for instance, a modified Murphy button. Of the animals Dr. Meyer had operated on, doing an esophagogastrostomy, the only one that had permanently recovered was the dog he presented. The operation on this animal was done on February 23. To-day the dog was in splendid condition. Dr. Meyer had done the typical operation in the lower third of the esophagus six times; three dogs made an operative recovery and had a well functionating anastomosis, which latter was secured by implanting the lower end of the proximal stump into the stomach. A positive universal differential pressure chamber was used in these operations. A description of the operation was illustrated by colored charts.

Primary Invagination of the Appendix Causing a Cecocolic Intussusception.—Dr. Hermann Fischer presented a patient, thirty-seven years of age. About two weeks before admission to the hospital she began to have pain in the epigastrium. In the course of a few days this pain became very intense and cramp like, and she vomited several times, food and bile. She often writhed in agony on the floor. At no time did the pain radiate to the shoulder, thigh, or bladder. It was at times relieved by pressure on the abdomen. Upon examination a swelling was discovered on either side of the inguinal region. It appeared to be a sausage shaped mass at the level of the umbilicus and it impressed one as being the transverse colon filled with feces. After thoroughly cleansing the bowel with cathartics and enemata this mass persisted. The diagnosis made was either intussusception of the colon or carcinoma. The patient suffered from partial obstruction of the intestine. The configuration of the mass was highly suggestive of intussusception, but there was no blood or mucus in the stools. At operation there was found an intussusception which reached almost to the splenic flexure. The appendix, which was very much distended and distinctly fluctuated, was partially invaginated into the cecum and held there by firm adhesions. On the assumption that he probably had to deal with a malignant growth, he resected the whole mass. The anastomosis

was effected by a lateral isoperistaltic iliocolostomy. The retrocolic space was drained. The patient made an uneventful recovery. An examination of the specimen showed that it consisted of a very much dilated invaginated portion of the appendix, which was considerably distended by a thick glairy mucus. This case represented an extremely rare condition, a cecocolic intussusception as the result of a mucocele of the appendix.

The Indications and the Time and Place for Amputations.—Dr. Jonathan M. Wainwright of Scranton, Penn., read this paper. He discussed the indications for amputations only for traumatisms as they occurred in civil practice, leaving out of consideration wounds by firearms and the treatment of pathological conditions. The modern treatment of open injuries had made a great change in the indications for amputations. At the present time one might fairly say that there was no single condition which absolutely demanded amputation. The old criteria such as complete circular division of the skin, injury to a large nerve or vascular trunk, or crushing of more than two inches of a large bone, should now never *per se* lead to an amputation. Those severe crushing injuries in which the vitality of the limb was hopeless were the only class of cases in which an immediate amputation was justified, and even with the hopeless crushing injuries, the practice should be different according to whether the crushed member was an arm or a leg. At times too much conservatism was employed in saving a very badly mangled leg, because a good artificial leg was often more serviceable and satisfactory than a very badly deformed natural extremity. In the arm the matter was quite different, especially if the crushing injury involved only the fingers and hand. In their service it had become quite rare to do a formal amputation of the fingers, hand, or forearm. The crushing injuries were carefully cleaned, loose threads of tissue were cut away, and loose fragments of bone might be removed, but the major portion of the wound was allowed to granulate. In this way parts of the hands or fingers could be preserved in a fairly useful condition, even though the process of granulation might take weeks or months. The only injuries of the arm in which immediate amputation was justifiable were those marked by severe crushes where there was no doubt whatever that the distal portion of the limb could not live. Even the severance of the axillary or femoral vessels or large comminution of bones did not demand immediate amputation. The first dressing should frequently be made under ether. The wound should be treated by thorough antiseptic methods, with free drainage, and the progress of the injured part should be carefully watched so that amputation need not be delayed for more than a few hours after it was evident that the injured part could not survive. Disaster would follow sometimes even with the most careful antiseptic treatment. He had seen gas bacillus infection carry off patients. A more difficult question which had to be decided from time to time was, if infection occurred should they amputate, and when and where? If the limb was still viable he believed efforts should be made to save it. The infection should be treated as in other cases by incision and free drainage. The death rate after secondary amputations was very high from sepsis, and they had found that in general lower mortality rates could be obtained by simply cutting away the limb at the point of injury and packing the stump wide open, with no attempt to bring the skin together. Free drainage was obtained in this way, and later, when infection had subsided or become chronic, a formal amputation could be done with much greater chance of recovery. The only question that should influence the time for amputation was that of shock. When shock was not to be feared he thought all surgeons were agreed that the injured limb should be amputated as soon as possible. If possible the surgeon's judgment as to the presence and degree of shock should be verified by blood pressure readings. An amputation at a given point in the arm would be accompanied by much less shock than an amputation at the corresponding point in the leg. In reference to shock the answer as to when to operate fell into three divisions. (1) Unless one had at hand materials for the modern treatment of shock and for nerve blocking, an immediate amputation should rarely be done; there should be delay for from twelve to twenty-four hours until these could be obtained. (2) In the absence of marked shock, immediate amputation could be done, provided the materials were at hand and the patient was in good condition. The advantages to the patient of immediate amputation were great both in regard to preventing the spread of sepsis and at once relieving him of the painful crushed limb. (3) When shock was already present, when the patient was first seen, experience seemed to indicate that it was always better to delay and allow partial recovery to take place. In some cases the expected improvement would not take place, and after twelve or twenty-four hours the patient was in a poorer condition than when first received. The fatal event in these cases would, however, probably be hastened by immediate amputation. These patients were now put to bed after the limb was cleansed and kept well under morphine. External heat was applied, water was given by the mouth, and enemas or intravenolis infusion, as might be indicated. The other extremities and the abdomen were bandaged. The so-called stimulants of a few years ago were rarely given. Concerning the place of amputation, as had been said, unusual latitude should be taken in an arm or hand, and in many injuries to the upper extremity it was better to allow nature to cover up the injured stump by granulation. In the lower extremity very satisfactory results had been obtained with partial amputations of the foot, especially those through the mediotarsal joint and those in which the os calcis was fixed to the sawed off end of the tibia. They had had a number of Chopart amputations who were doing rough work in the mines, with practically no inconvenience. He believed that one cause of trouble from partial amputations had arisen from the contraction of the tendo Achilles. This tendon should always be cut in these partial amputations of the foot. When it was necessary to do amputation above the ankle, satisfactory stumps could be obtained if at least eight inches of the tibia could be left. If the amount of tibia that could be left was much less than this, better results could be obtained by means of a knee amputation of the Gritti type. When an amputation had to be done above the knee it was very important to preserve every inch of the femur possible in order to obtain leverage for an artificial leg.

The Technique of Amputations, with Special Reference to Osteoplastic Methods.—Dr. Alexis V. Moschcowitz read this paper. (See page 1017.)

Results of Amputations in Sarcoma, Diabetic Gangrene, and Sepsis.—Dr. Burton J. Lee read this paper. Sarcomata.—This series included 21 cases, 13 males and 8 females, all save four being under thirty years of age. F. Murphy gave the immediate mortality for new growths of the lower extremity as between 15 and 16 per cent., with a total of 44 cases. Von Bergman gave the immediate mortality with interscapulothoracic amputations as 4 per cent. Jeanbrau gave 7.8 per cent. mortality for the same operation. Recurrences depended of course largely upon the type of sarcoma and the age of the patient. Bloodgood believed that tumors which were permanently cured by operation were of like pathology, while those which exhibited recurrences were pathologically different and would recur whatever operation was performed. Ten cases were available up to the present time for complete study.

and of these one died in a few hours, and another of puerperal sepsis at five months, two weeks after operation. Of the eight remaining cases, recurrences took place in five. Bloodgood believed that a conservative operation would leave as good results as amputations, while in tumors of marked malignancy, in spite of high amputation, patients succumbed. Babcock and Pfahler took the same view. They added that sarcomata of the very malignant type were most prone to disappear or retrogress, and believed that operative traumatism was the most powerful local traumatizing agent. They believed that a combination of judicious subscapular enucleation, massage, and prolonged Roentgenism, topical applications of methylene blue or pyck-tannin, administration of drugs and toxins offered results superior to those obtained by the most extensive and desperate surgical eradication. One seemed impelled to decide against amputation in sarcomata, save in those cases where the limb was rendered functionless from the presence of the new growth. The main hope seemed to lie in the laboratory study of the problem of new growths. Diabetic Gangrene.—There were 13 cases, 10 males and 3 females, with an average age of 53 years. Ten of the cases involved the lower extremity, while three involved the upper. The immediate mortality (within two days) was 15 per cent., two dying within three days. The presence of acetone bodies in the urine seemed to bear a direct relation to the immediate mortality. None of the 13 cases lived longer than nine weeks. Such a record was certainly discouraging. In this series the amount of glucose present in the urine seemed to bear little relation to the severity of the symptoms. Sepsis.—This group embraced 12 cases, all males, one-half the patients being under thirty-five years of age. In the immediate results one found a very unpleasant mortality of 80 per cent. This mortality would surely be reduced if earlier operations could have been performed. In many instances conservative operations were repeated several times before the ultimate amputation. The study of this series must impress one with the fact that amputation should not be deferred too long, for if one waited until the condition was almost hopeless amputation must avail but little. The results in the treatment of sepsis with vaccination with dead organisms did not offer much hope at present. With a rapid advance in the infection, uncontrolled by free incisions and ordinary conservative surgical measures, amputation should not be deferred.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 11, 1909.

DR. ELI LONG IN THE CHAIR.

Cerebral Diplegia.—Dr. MATTHIAS NICOLL, JR., presented a boy, three years old, a mulatto, who was admitted to an institution when seven months of age. The first recorded history was in May, 1908, when he was eighteen months of age; then the statement was rendered, "subluxation of shoulder, anterior poliomyelitis, rechitis." The subluxation was marked and there was slight power in extension of the wrist and in supination. He had a marked rachitis and a lumbar kyphosis probably due to the latter condition. The history obtained from the outside nurse was that the child had an attack of whooping cough when about nine months old when it was noted that he did not move his arm. Both legs were also involved, although apparently at the present time gaining in motion. The reflexes were exaggerated. The child talked but little and his intelligence was limited.

Dr. NICOLL also presented a girl, six years old, who had been admitted to the hospital when three weeks of age. Her birth history was not known. The paralysis was first noticed by the wet nurse when the child was eight months of age; the child was then returned to the hospital and had been under observation since. Until the past year she had not made any attempts to stand even with support. Her intelligence had developed slowly but steadily and was now of a fair order. Both patella reflexes were exaggerated. Her method of walking was demonstrated.

Dr. WILLIAM P. NORTHRUP said that he had lectured for three years on the second case presented by Dr. Nicoll. During that time he had not been able to help her very much. He was glad to note some improvement in her condition now. He concurred in the diagnosis made, but could see no future for the child.

Dr. REGINALD H. SAYRE said that in a good many of these spastic cases it seemed to him improvement would follow stretching the legs and keeping them stretched for a good part of the day, so as to overstretch the contracted muscles in order that the anterior skin group and the extensors of the thigh could act without undue opposition. Systematically teaching such patients how to balance and stand resulted favorably. He had seen many patients make good progress; they could get around without assistance, without handling anything, walking without artificial support. He believed that such children could be greatly benefited by stretching these contracted muscles and teaching them to coordinate their movements. Mrs. Seguin of Orange got marvelous improvements in cases with spastic conditions. In this case the calf muscles were so contracted the patient could not put the heel to the floor. Dr. Sayre thought by stretching these muscles the heel could be placed upon the floor and the patient enabled to hold her balance better than she now did. In the present case tenotomy probably would not be necessary. The coordination of movements was to be taught by exercises very similar to those used by Frenkel in cases of locomotor ataxia.

A Case of Extensive Paralysis Due to Anterior Poliomyelitis.—Dr. OSCAR M. SCHLOSS presented this patient for Dr. Roland G. Freeman. This was a case of anterior poliomyelitis with extensive paralysis which involved the thoracic respiratory muscles. The onset of the disease nine weeks ago was sudden with fever, convulsions, vomiting, and diarrhea; these symptoms lasted three days. Then the mother noticed that the child was unable to hold up its head, that all four extremities were paralyzed and that the respirations were rapid. When admitted to the clinic the child could move the hands and feet, but otherwise the extremities were powerless. The respirations were entirely diaphragmatic, and the anterior neck muscles were paralyzed. None of the reflexes could be obtained in the arms. Sensation seemed to be intact. During the three weeks the child had been under observation there had been a noticeable improvement.

Cases of Paralysis of the Abdominal Muscles.—Dr. PEASE presented three such cases for Dr. Henry Dwight Chapin. The paralysis resulted from anterior poliomyelitis.

Dr. WILLIAM P. NORTHRUP said that he had probably seen four or five cases of complete paralysis of the thoracic muscles, the work of respiration being done by the diaphragm. Dr. Northrup presented some photographs taken of three cases of paralysis of the abdominal muscles due to poliomyelitis.

Dr. HENRY W. FRAUENTHAL presented seven photographs of children with hernia or bulging through the abdominal wall, similar to the cases shown by Dr. Northrup. He presented a case similar to Dr. Chapin's with paralysis and atrophy of the thoracic muscles. This patient had all the muscles of the extremities and trunk involved. The diaphragm was still involved. Under massage, high frequency, and sinusoidal electricity he finally regained perfect use of his legs and left arm. The right arm was still involved. The pectoralis major and minor muscles, together with the

other muscles of respiration, have not as yet responded to the treatment; hence, the appearance of the chest and his abdominal breathing.

The New Treatment of Spastic Paralysis by Resection of the Posterior Spinal Nerve Roots.—Dr. L. Pierce Clark read this paper. He said there was a two-fold motor disturbance in the extremities as a result of damage or destruction of the anterior pyramidal tracts, namely, contraction and weakness of various muscles. The character and completeness of the injury to the pyramidal tracts gave the peculiar type of contraction and paresis of the different muscles, in the several types of spasticities. When the pathway of excitability of muscles from the cortex by way of the pyramidal tracts was destroyed or severely damaged, the irritability of the muscles from the periphery, as the result of sensory impressions, was not only preserved, but was more or less heightened. The pyramidal path also inhibited the lower spinal reflex and in the lessened control permitted an insubordinate activity of the lower spinal centers. The objective evidence of the enhanced reflex irritability in the lower arc was shown in the spastic syndrome of increased knee jerk, ankle clonus, Babinski reflex, etc. As a rule the greater the absence of voluntary motion, the greater the reflex activity. Aside from the involuntary associated movements in the diplegics, they had a more or less late, but permanent, spastic muscular contracture which did not disappear under ether narcosis. These contractures prevented motor functions by offering more or less resistance to extension. The inhibiting function of the pyramidal tracts was independent throughout of the function producing spasticity. When the seat of entry of the posterior or sensory roots were diseased, as in tabes, the reflexes were abolished. Many surgical procedures had been undertaken to restore the normal balance in the spinal reflex arc in diplegia. The posterior sensory roots were the points of attack if one sought the sensory side of the arc. The best point of attack on these sensory nerves was in the spinal canal, dorsal to their ganglion. Dr. Taylor, therefore, operated at this point. Dr. Clark presented two cases. The first was a boy eleven years old whose history was negative except a cerebral diplegia secondary to meningoencephalitis induced by a very severe attack of malignant scarlet fever when he was eleven months old. His paraplegic syndrome was typical. He was able to walk by taking very short steps with arms extended. Various orthopedic measures had failed to help him. The dorsal roots of the left side were resected; they were the last dorsal and five lumbar. Dr. Taylor performed the operation August 23, 1909. One week after there was found to be a greatly reduced spasticity in the whole left leg, there was a great reduction in the reflexes, and there was an absence of ankle clonus and an imperfect production of the Babinski. The patient now stood and walked alone. The second case was an eighteen year old boy who had suffered from left hemiplegia from birth. The typical infantile syndrome developed. The whole left upper extremity was in a "birdwing" contracture and spastic. Three days ago Dr. Taylor resected the dorsal nerve roots from the fourth cervical to the second dorsal inclusive. The arm now was entirely free from spasticity. Tenotomy, physical training, and orthopedic appliances would be employed.

The Surgical Technique.—Dr. Alfred S. Taylor said that the technique in resection of the posterior spinal nerve roots differed somewhat from that of an ordinary laminectomy; in the latter they removed the spinous processes and more or less of the laminæ of both sides. Dr. Taylor thought that if he could get sufficient room through a unilateral exposure, he would not only come directly down upon the nerve roots but could leave the spines intact. The operation consisted in making a longitudinal incision just to one side of the spinous processes, separating the muscles from the spinous processes, retracting them outward to the articular proceses; then, by means of a Doyen saw, he cut through the laminæ at the base of the spinous processes, and also near the articular processes. One might get from one-quarter to one-half an inch of room by cutting outward toward the articular processes. After making a double line of sections, the parts could be lifted and removed. The dura thus exposed was slit and the spinal cord fully exposed. The lower cord could be turned 90° without injury to the lumbar enlargement. He believed this method was adaptable for exposing tumors of the spinal cord. After an ordinary laminectomy there resulted a marked deformity of the back, and a part of the cord was not protected by bone. Dr. Taylor presented a patient upon whom he had performed a limited resection. There was no loss of function in the spine. He also presented cases suitable for operation, one being a case of infantile cerebral diplegia and one an epileptic.

Dr. Charles Ogilvy said that when he saw the patient presented by Dr. Taylor some time ago he had been unable to walk without a shuffling gait and had great difficulty in raising the feet from the floor. The spasticity was then more decidedly marked than it was at present. Dr. Taylor certainly made a very beautiful exposure of the cord, and the hemorrhage was much less than was encountered in doing an ordinary bilateral laminectomy.

Dr. Joseph Fraenkel said that in order to understand the rationale of this mode of treatment of spastic paralyses, it would be necessary to say a few words about the diagnostic and prognostic interpretations of the reflexes. Ten years ago Dr. Fraenkel made a study of the relationship of the tonus of the tendons to the reflex phenomena by means of an apparatus devised by Dr. Moskens of Utrecht. (See Medical Record, December 12, 1903.) Among the conclusions reached in this study, the one having particular reference to the subject in question read: "That disease of the pyramidal tracts causes hypertonia and increase of reflexes. The tendon jerks under such conditions are increased unless additional disease of the ascending tracts, anterior horns, or some part of the peripheral neurons neutralizes this influence." The loss of motor function in spastic conditions was in direct proportion to the reflex spasticity. It appeared then rational to add sensory disease wherever the loss of motor function was considerable. From this theoretical consideration he hestitated to take the practical step because there was uncertainty as to the outcome and difficulty in finding a quantitative gauge. Dr. Beer, at Dr. Fraenkel's suggestion, tried the influence of stovain injections into the nerve or cerebrospinal fluid. The immediate results obtained were quite convincing in the shape of marked return of motion, disappearance of spasms, ankle clonus, and Babinski sign. These beneficial results lasted, of course, as long as the influence of the stovainization and with the disappearance of the anesthesia thus produced, the spastic phenomena became reestablished. He said he was glad to hear that the experiments on the living, and the work done by Foerster, gave further corroboration of the correctness of this therapeutic measure. It would be necessary, however, to be very careful in the selection of cases adapted for this mode of interference. First of all, it appeared that cases of extreme spastic contractures would derive benefit from posterior nerve cutting by having their inordinately stiff, useless extremities changed into more or less flaccid ones. Cases with subcortical sensory implication should be excluded on account of the irritative motor phenomena (chorea, athetosis, etc.) arising from such lesions and the liability of their becoming aggravated by additional sensory disease. Concerning the operative technique he emphasized the fact, that the severance had to be made so that the intervertebral ganglion was left in connection with the peripheral stump, in order to avoid distrophic consequences.

Dr. Virgil P. Gibney said all were willing to wait and see what results were obtained; at present they promised to be favorable. He had never seen a case of spasticity overcome, although he had noted improvement in some cases. He had divided the hamstring muscles, the tendo Achillis, the adductors of the thighs, and had even removed the tensor vagina femoris *en masse* to get rid of the spasticity; the correction lasted for months, sometimes even for years, but it would return and he became very skeptical about ever being able to abolish it finally.

Dr. Edward D. Fisher said that the operation was one that was likely to produce a temporary paralysis, but even that might be better than the spasticity, especially in the more severe cases. The operation cut off the sensory impulses passing to the brain. This was a proper physiological basis for the operation. Two things had been accomplished, muscular flaccidity and the removal of irritating impulses to the brain. The contractures were caused by sensory impulses passing to the brain and then passing down the cord as motor impulses, and again caused by impulses from the brain itself primarily. The value of the operation, therefore, was a double one. It first reduced the spasticity and might also improve the cortical condition, not by regenerating the cells, but by removing the source of irritation and giving the cells a rest. It might thus have an influence in reducing the tendency to epileptic seizures. In observing the boy Dr. Taylor presented, he noticed the reflexes were returning. It was possible all the sensory fibers did not decussate in the spinal cord. The question of the removal of sensory irritation had been taken up by other methods and with the same results. It made no difference whether it was by cutting the posterior spinal nerve roots, or by destroying the nerve itself, or impairing its function. In these cases he thought the operation justifiable and that there was hope for it in the future. The selection of appropriate cases was very important. Those in which there was the least mental improvement would prove the most successful.

Dr. T. Halsted Myers said that these cases divided themselves into classes according to degree, and some cases could be improved by educational methods and braces. In the severer contractures one must decide whether there was a permanent structural muscular change, or whether the deformity was due to the spastic condition itself. If there were structural changes in the muscles, he thought an operation was indicated and should be the first step taken, making full division of the tendons and muscles. If sufficient improvement did not result the operation described by Dr. Taylor might help.

Dr. Samuel Lloyd said he was very much interested in the work previously done along the line of section of the posterior nerve roots. In this work there was to be considered the question of regeneration, and just how much this would bring back the spastic condition of the patient at a later date. The operation might give a cortical rest and, in that way, it might cause an improvement in the spasticity. They should, however, wait and learn what the conditions were. The question of regeneration of the posterior spinal nerve roots and destruction of the cord, which many had in mind, was a very interesting one. It had been suggested by Dr. Dana, and tried by Dr. Abbe and others; in fact, the hope had been raised that by using the posterior spinal nerve roots impulses might be carried to the destroyed segment of the cord, and in that way impulses might be gotten to the lower cord. In the cases experimented on, however, they had gotten no such results. In the operation it was seldom they met with a hemorrhage that was at all embarrassing. Removing a full lamina gave a field of approach to the spinal cord and enabled one at once to get at the posterior spinal nerve roots without difficulty and without rotating the cord 90°. It was true that the upper part of the cord was not so movable as the lower portion. If the spinous processes were cut through at their bases, the deformity was not great, the laminæ were replaced in time by bony regeneration, so that the spine was not weakened and there was no danger from trauma.

Dr. L. Pierce Clark, in closing the discussion, said that one should remember that the resection of the dorsal nerve roots was done dorsally to the sensory nerve ganglion and that this point of resection insured absolutely no regeneration of the nerve or return of the former spastic element. Furthermore, the ganglion being upon the peripheral portion equally insured against the supervention of trophic changes in the peripheral structures. The work was to continue on a large series of cases and scientific reports would be issued from time to time.

Dr. Alfred S. Taylor, in closing his part of the discussion, expressed his appreciation of the discussion which had suggested much of value for future work. Concerning the technique, he wished again to call attention to the fact that Tietze had complained of the unsatisfactory approach to the posterior roots by means of the usual bilateral laminectomy; whereas his own (Taylor's) method brought the operator directly down upon the roots sought, and the roots of the opposite side could be divided if necessary through the same incision. Replying to the remarks in favor of bilateral laminectomy, he stated that the method which gave the most convenient exposure with the least loss of bony structure was certainly to be preferred, and that unilateral laminectomy fulfilled these conditions.

GENITOURINARY SECTION.

Stated Meeting, Held April 21, 1909

Dr. Martin W. Ware, Chairman.

Symposium: Treatment of Gonorrhea in the Out-Patient Departments of New York City.—Dr. James R. Hayden said that the method of treatment employed at the Vanderbilt Clinic for specific urethritis was based upon the pathology of the disease, or the manner in which the gonococci invaded the tissues after their implantation upon the mucous membrane of the fossa navicularis. The disease was divided into four stages, as follows: First, the serous or prepurulent stage, in which the patient had a slight serous discharge and in which the gonococci were free and superficially seated upon the mucous membrane of the fossa navicularis. Second, the stage of acute suppuration, in which the discharge was purulent and the gonococci having penetrated the cement substance between the epithelial cells, were deeply seated. Third, the stage of decline in which the discharge and acute inflammatory symptoms were markedly decreased and, fourth, the chronic stage in which the discharge was slight and the urine was clear and contained flakes. The treatment of gonorrhea depended entirely upon the stage of the disease in which the patient was seen. If he came during the first or serous stage which was rarely the case, then abortive treatment with silver nitrate might be employed. This, in the speaker's opinion was the only period in which the gonococci could be destroyed on account of their superficial situation. In the second or acute inflammatory stage the gonococci were too deeply seated to be acted upon by irrigations or injections of any kind, and their employment at this time simply washed off the mucous membrane and added a traumatic inflammation to the already intensely congested and swollen canal. In this stage, therefore no local treatment was ever employed. The patient was told to keep as quiet as possible especially during the first few days and to drink a glass of still water every hour which flushed out the urethra in a normal manner from above downward. An alkaline mixture was ordered to render the urine bland. The bowels were kept open by cathartic pills and the testes worn in a suspensory bandage.

The diet was light and non-irritating but nutritious and alcoholics, charged waters, coffee, chocolate, and cocoa were prohibited. The penis was immersed in a hot lead solution three times a day and the patient given a printed list of rules and carefully instructed as to his mode of life diet medication etc. The penis was so dressed with gauze as to allow free drainage of the discharge. This stage lasted from seven to fourteen days, during which time the penile and urethral inflammation was treated like inflammations elsewhere in the body. In the third, or stage of decline, the alkaline mixture was replaced by the antiblennorrhagics which were most useful at this time, but which should never be given during the acute inflammatory stage. The patient was now told to use hand injections of dilute lead water at first, and later, mild solutions of zinc, alum, and, finally, permanganate of potash. After a few days of the above hand injections, the anterior urethra was irrigated by means of a small rubber catheter and hand syringe, with potassium permanganate, and finally with silver nitrate, which latter caused an absorption of the submucous exudate and a restoration of the damaged mucosa. In the fourth, or chronic stage, the antiblennorrhagics and irrigations were stopped, and the patient given instillations of silver nitrate with a small soft rubber catheter and instillation syringe. Full-sized sounds and the endoscope were employed when necessary. Specially constructed dilators were never used. When acute posterior urethritis developed, as it frequently did, all local treatment was stopped, as were also the antiblennorrhagics. The patient was kept very quiet, or, if possible, put to bed and given an alkaline mixture with uva ursi and triticum repens. Hot rectal irrigations of normal salt solution and the hot sitz bath gave much relief. When the acute symptoms had subsided, the patient was allowed to be up and about, and the bladder and urethra were irrigated with a soft catheter and hand syringe, using mild solutions of zinc, alum, potassium permanganate, and, finally, silver nitrate. The speaker was convinced that by treating gonorrhea according to its stages, and not in a haphazard and irrational way by the gonococcocides, his patients were cured just as rapidly and more permanently, and the urethra and its contiguous glandular structures, especially the prostate, was left in a more normal condition, the practical results of which meant fewer cases of chronic urethritis and stricture of the urethra.

Dr. Frederic Bierhoff, discussing the treatment of gonorrhea in his class at the dispensary of the German Hospital, said it had always been his aim to make an accurate diagnosis of the conditions presented as a basis for intelligent treatment. With that object in view, a microscopic examination was made in each case presenting even a trace of discharge, in order to determine the presence or absence of gonococci. If they were found at the first examination, the further measures were proceeded with; if not, the patient was put upon the alcohol test, with the use, by the patient himself, of an injection of a disinfecting solution, such as bichloride, 1-20,000. If no gonococci appeared, then an irritating anterior irrigation of nitrate of silver solution, 1-5,000, was employed. Should no gonococci appear even now, microscopic examinations were still made at intervals, for it had been repeatedly found that, particularly in cases in which the balsams had been employed internally, or astringents locally, during the acute stage, the microroganism might appear after repeated tests. Should gonococci be found, the treatment should be begun at once. Any delay simply invited the extension of the disease to the deeper tissues, or to the adjacent organs. By employing the gonococcoide drugs only during the infectious stages of the disease, we rapidly disinfected the canal, lessened the tendency for the disease to extend, and, he felt convinced, lessened the complications. He had never been able to satisfy himself that the balsams or alkalis were needed, or that they were of any definite value in the cure of a gonorrheal process. If the treatment directed against the gonococcus was begun early, the pain, ardor urinæ, etc., rapidly disappeared, and chordee was almost unknown. Of the newer gonococcocides he had discarded all that had any decided astringent action. If the process did not quickly subside under the use of organic silver irrigations and injections, he made use of the Kollmann anterior irrigating dilator, advancing the degree of dilatation slowly. If the gonococci still persisted under this treatment, the urethra was examined through the endoscope, and the infected glands and lacunæ were either slit up or destroyed by electrolysis, acording to their size.

Dr. George K. Swinburne of the Good Samaritan Dispensary said that every man learned to treat his cases of gonorrhea in his own way. He had long since given up the use of astringents and the balsams. The main factor in the treatment was the utmost gentleness, especially in the earlier stages of the disease, and the chief desideratum was to obtain a cure in the shortest possible time and with the least possible damage to the tissues. He believed that the best method of treatment, especially in dispensary work, was the use of the silver salts at any stage at which the patient presented himself. The discharge itself did not constitute the disease; it was nature's method of curing the disease. As a matter of fact, the use of all these salts was followed by a certain amount of secretion of a mucoid character, which was apparently beneficial to the patient. The injection of the silver salts allayed the inflammation and added to the comfort of the patient. He did not consider them responsible for the various complications which might occur; these he had seen follow every method of treatment. In a case of gonorrheal prostatitis he had seen the symptoms rapidly improve under the use of Roger's serum.

Dr. Benjamin S. Barringer of the dispensary of the New York Polyclinic said that in acute gonorrhea, whether anterior, or anterior and posterior, if the symptoms were very acute, with tenesmus and burning, the patient was instructed to drink large quantities of water, and was ordered a non-irritating and non-alcoholic diet. As a rule, he was also given an emulsion of the oil of gaultheria, and if that did not control the burning, etc., a prescription of tincture of hyoscyamus and potassium citrate was added. A routine examination for gonococci was not made unless some special feature of the case indicated it. Injections, as a rule, were not given in the early stages. When the early acute stage had subsided, if the patient was fairly intelligent, he was given an injection to use at home. In the sub-acute stage, when the gonorrhea was anterior (to which region it was rarely limited in dispensary patients), the hand injections were continued, using at first protargol; then, if necessary, potassium permanganate or the astringents. If the gonorrhea was anterior and posterior, a rubber catheter was used to inject fluids into the bladder. Chronic urethritis was treated by both instillation and bladder injections. Complications were treated as they arose and according to the indications.

Dr. Francis C. Edgerton of the Cornell University Dispensary said that in the treatment of gonorrheal urethritis at the clinic with which he was connected there were four points upon which he wished to lay great stress: 1. The necessity of dilute urine. 2. The great damage done by over-distention of an acutely inflamed urethra. 3. The early recognition of a posterior urethritis. 4. The necessity of regular attendance. There was nothing better to dilute the urine than plain water, providing it was taken in sufficient quantities. To avoid over-distention of the urethra all injections into the anterior urethra were given with a syringe which contained but one dram, and only one-half of its contents was injected. When it was neces-

sary for a patient to use a hand injection, he was given a dram syringe and instructed never to use it more than half full. The speaker said he believed the posterior urethra was involved in the greater number of cases of gonorrheal urethritis that had lasted ten days, where the first urine was still very cloudy, due to pus, although the second urine might be clear, and we had practically no subjective symptoms. All uncomplicated cases of anterior urethritis were treated immediately by injections of an organic silver salt. In the acute cases a 5 to 10 per cent. solution was used, but after two or three days, when the acute symptoms had subsided, a weak solution of from ¼ to 2 per cent. was more satisfactory. During the acute stage the patient was not allowed a hand injection. In a very acute posterior urethritis, with tenesmus or frequency, rest was imperative, and a mild sedative was given internally. No local treatment was used until the acute symptoms subsided. He believed that a beginning posterior urethritis could many times be aborted by instilling from 10 to 20 drops of a 10 per cent. solution of a silver salt into the posterior urethra. He emphasized the importance of making a fresh solution of the silver salts; otherwise it irritated the urethra and did more harm than good. The treatment of chronic gonorrheal urethritis involved not only the treatment of the urethritis itself, but of all the complications of gonorrhea.

Dr. Alfred T. Osgood, representing a part of the dispensary service at Bellevue Hospital, said his effort was to combine the palliative treatment of gonorrhea with energetic local treatment. Internally, sandalwood oil was given and copious water drinking was advised, combined with as much rest as possible. As a gonococcocide, organic silver compounds were preferred, and given both by injection and irrigation. The treatment was kept up as long as the gonococci could be demonstrated in the discharge. Astringents were not given as a routine measure, but when one was indicated zinc sulphate was preferred. The abortive treatment was practically never resorted to. The posterior urethra itself was not treated by any local applications, dependence on a cure being placed on more conservative methods, *i.e.* rest, low diet, plenty of water, and sandalwood oil. In the chronic form an effort was made to medicate the infected area directly through the endoscopic tube.

Dr. Arthur H. Cilley, speaking for a part of the dispensary service at the Postgraduate Hospital, said that in his class he saw very few cases of gonorrhea in the early stage of the disease. Usually, the infection was well advanced to the second stage described by Dr. Hayden. As a rule, during this stage no active treatment was undertaken. The patients were first given the salicylate of soda, followed by sandalwood oil or the balsam of copaiba. In some cases a hand injection of a silver salt was given during the early stage of the trouble, but as a general rule no attempt was made to check the discharge immediately, partly because these dispensary patients could not be trusted. It was usually easy to check the discharge fairly promptly, but it was very apt to return, and in the meantime many of this class of patients would not hesitate to have intercourse and infect some one else. When the posterior urethra was involved, an attempt was made to get at the exact state of affairs by a rectal examination. Gonorrheal rheumatism he was inclined to attribute to involvement of the seminal vesicles, and the treatment consisted of mild strapping. In concluding his remarks, Dr. Cilley referred to the fact that the night dispensary classes were usually so overcrowded that the treatment could not be carried out as thoroughly as might otherwise be done.

Dr. Victor C. Pedersen of the New York and Hudson Street Hospitals emphasized the importance of properly instructing the patient. At the House of Relief, where about 8,000 of these cases were seen yearly, the new patients were in a room by themselves, and were given personal advice by the Chief of Clinic. Printed leaflets were given each patient. The good effect of such a course had already been noted. Patients sought relief earlier, they were more apt to remain until they were thoroughly cured, and, as a consequence, tight strictures, for example, were becoming more rare. Speaking of the infection itself, Dr. Pedersen said that Rogers and Torrey had recognized different strains of gonococci, the virulence of which varied widely. Hence until we learned to recognize virulence early, treatment would vary greatly. In the treatment of a gonorrheal patient the dressing was very important. Instead of the use of absorbent cotton, which kept back the discharge and was probably a potent factor in the causation of complications, the speaker favored the use of a piece of gauze six or seven inches square, with a hole cut in the center, through which the glans penis was passed. The gauze was then loosely gathered about the organ. Rest in bed was the ideal treatment, but it was usually beyond the reach of a dispensary patient. Free water drinking should be advised, and as an alkali he preferred the bicarbonate of sodium. Hand injections were used, as a rule, only after the subacute stage had begun. The vaccine and serum treatment of gonorrhea was still in its infancy, and doubtless promised a great deal in the future for the cure and, perhaps, prevention of the disease.

Dr. Martin W. Ware, representing a part of the dispensary service at Mt. Sinai Hospital, said the recognition of the gonococci as the causative factor was the paramount feature of this entire subject. As soon as the case was recognized as one of *bona-fide* gonorrhea, injections of silver were begun, and the prolonged application of the drug, as enunciated by Neisser, was advocated. To effect this the lips of the meatus were sealed with a small clip, and the injection was kept in the urethra for fifteen minutes. A fresh solution was prepared daily. The fact should be borne in mind that many dispensary patients were badly nourished. A complicating epididymitis was treated by Bier's hyperemic method. When the follicles were invaded, as determined by endoscopy, applications of silver nitrate or iodine were made, and in suitable cases dilators were used. If home treatment was necessary, the patients received careful instruction. The sandalwood preparations were never used. In spite of every available method of treatment, there were certain cases of gonorrhea that apparently could not be cured, and he had in mind one case in which the discharge had persisted for eighteen months, in spite of the use of serums, vaccine, and everything else.

Dr. H. Goldenberg emphasized the three following points: 1. To make the diagnosis by microscopic examination. 2. To localize the disease, whether anterior, anterior and posterior, with or without involvement of the prostate or seminal vesicles. 3. In the treatment to use gonococcicides at an early stage. Taking up the various statements of the speakers, he regarded Dr. Hayden's division of his cases into four stages as too schematic. The principal consideration was the question, were gonococci present or not, the stage of the disease being of secondary importance. Like Dr. Hayden, he favored gentle methods of treatment, but not in the form of astringents in the beginning, which practice he condemned. There was a medium between the "rough" and the too conservative methods. In his experience, complications, such as epididymitis, were more frequent if internal medication only was employed in the beginning, and with the early use of the astringents the disease ran a much more protracted course. In general, he agreed with Dr. Bierhoff's views. The statement of Dr. Barringer that most of his patients had anterior and posterior gonorrhea made the speaker believe that this was due to the fact that the active treatment was too long deferred

in his cases. With Dr. Edgerton, he took issue regarding his statement as to the capacity of the anterior urethra, since in his experience it was two or three times as large as stated. Replying to Dr. Cilley's statement that the night classes at the Postgraduate Dispensary were overcrowded, he advised the adoption of a rule to limit the number of patients who were admitted.

Dr. James Pedersen said the treatment of gonorrhea should be, in his opinion, a composite treatment, *i.e.* an adaptation of one or more of the different methods that had been referred to by the various speakers to the particular case in hand. Personally, he divided the course of the disease broadly into the acute, subacute, and chronic stages. In the acute stage he advocated one or another of the silver albuminoid compounds by the hand-injection method with a two-dram syringe, the patient being carefully instructed how to use it. The injections were continued for many days after the gonococci had disappeared from the discharge. In the subacute stage he favored very mild astringents, and in the chronic stage nitrate of silver, with or without dilatation, according to the conditions present. He was strongly opposed to irrigations in the acute stage. Acute posterior urethritis he let alone unless the patient was suffering severe tenesmus, in which case he instilled a mild solution of albuminoid silver. In his experience, patients were rarely seen early enough to make it possible to abort the disease; he preferred the term "inhibition." This was accomplished by the various silver albuminoid compounds, through their prompt destruction of the gonococcus.

Dr. Robert H. Greene said that, strangely enough, he agreed with almost all the preceding speakers. In the past one hundred years medicine had made its greatest advances along preventive lines, and he considered the idea of prevention as applied to the treatment of gonorrhea more valuable than direct local treatment of the disease itself. The main object we should have in view was to protect the prostate, the posterior urethra, and the bladder. The after result of chronic inflammation of the deep urethra, prostate, and bladder were enlargement of the prostate in the aged, tumor formations in the bladder, and in quite a large proportion of the cases malignant growths as an end result. In one particular he wished to disagree very emphatically with the remarks of the preceding speakers. While none of them had made a positive statement to that effect, the impression gathered from listening to the papers was that posterior urethritis was a somewhat unusual complication of gonorrhea, when, as a matter of fact, posterior urethritis was present probably in the majority, if not all, cases of gonorrhea that came under treatment. In a series of 116 cases examined by him a few years since for the purpose of determining the extent of the inflammation, the posterior urethra was found involved in from 40 to 50 per cent. His observations since had been such as to teach him to believe that the proportion was much higher than this, and that probably in all cases of gonorrhea the posterior urethra was more or less involved. The two-glass test so frequently mentioned as of diagnostic aid was extremely misleading. If there was only a small amount of urine in the bladder, and the patient was allowed to urinate in two glasses, the first glass would be cloudy and the second glass would be clear, whether the posterior urethra was involved or not. He thought it very much better carefully to wash out the anterior urethra as far as the bulbomembranous juncture, and then instruct the patient to urinate in three glasses. Any products of inflammation then found in any of the glasses would be evidence that the inflammation had extended beyond the anterior urethra. As a general rule, he thought we were apt to overtreat our gonorrheal patients in the early stages of the disease, and to discharge them too soon.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Colorado State Board of Medical Examiners.

October 5, 1909.

ANATOMY.

1. Describe the clavicle, naming the muscles and ligaments attached to it.
2. Name the muscles attached to the tibia.
3. Describe the hip joint.
4. Give the boundaries and contents of the popliteal space.
5. Give the origin, insertion, and nerve supply of the following muscles: Sartorius, triceps (in arm), gastrocnemius, pectoral muscles.
6. Give the relations of the heart to the chest wall, and name the valves of the heart.
7. Describe the brachial plexus.
8. Describe the diaphragm; mention its attachments and openings and tell what they transmit.
9. Give the relations of the prostate gland.
10. Name the structures seen in a cross-section of the thigh at its middle.

PHYSIOLOGY.

1. Give a physical description of the blood, together with its functions.
2. Give (*a*) origin, function, number per c.m.m. of red blood corpuscles, (*b*) origin, classification, function, and number per c.m.m. white blood corpuscles.
3. Give the forces which cause the blood to circulate in its vessels.
4. Give a physical description of lymph, together with its functions.
5. Define respiration, its function, and tell how performed.
6. Name the digestive ferments, tell the origin and function of each.
7. Name the organs of elimination and tell the function of each.
8. Give the function of (*a*) the liver, (*b*) spleen, (*c*) thyroid gland.
9. Give the distribution and functions of the first five cranial nerves.
10. Give a short description of the vasomotor nervous system, with its functions.

CHEMISTRY.

1. What is the chemistry of Fehling's test for glycosuria?
2. Give a test for chlorides in water.
3. Name the principal chemical constituents and their average percentage in the stomach three hours after a meal of mixed food.
4. What is the significance of nitrites in drinking water?
5. Name the principal chemical constituents, and their average percentage, of normal urine.
6. What chemical reaction takes place when solutions of ammonia and acetic acid are mixed?
7. What is the chemical composition of the various renal calculi?
8. What is percentage of albumin in normal blood serum?
9. Name tests for albumin in urine other than nitric acid and the application of heat.
10. What is a base? an acid? an alkali? an acohol? an ether?

TOXICOLOGY.

1. Define toxicology.
2. Give symptoms of an overdose of chloroform, and treatment.
3. Give post-mortem appearance in a case of death from chloroform.
4. Give symptoms of poisoning by oxalic acid, and treatment.
5. Post-mortem appearance in death from an overdose of oxalic acid.
6. Give symptoms of poisoning by acetate of lead, and treatment.
7. Post-mortem appearance in death from acetate of lead.
8. Give signs of death by drowning.
9. Give symptoms of one asphyxiated by vapor from burning charcoal.
10. Post-mortem appearance of one asphyxiated by charcoal vapors.

SYMPTOMATOLOGY

1. What is pseudoleucemia and what are its principal symptoms and prognosis?
2. Differentiate bronchopneumonia from acute lobar pneumonia and capillary bronchitis.
3. What is exophthalmic goiter? Give its principal symptoms.
4. Give the etiology, symptomatology, and prognosis of tabes dorsalis.
5. What conditions commonly cause icterus?
6. What are the general classes of diabetes and how is each diagnosed?
7. Define variola; describe the stages of this disease.
8. Name the exanthematous diseases of children and give the symptoms and differential diagnosis of each.
9. Name the different forms of nephritis; give the symptoms and differential diagnosis of each.
10. Discuss the diagnosis of the following case: The patient is a married woman, age 34, large and fat in person. She has had two children and three miscarriages, the last six weeks ago. Otherwise she says her health has always been good until within three or four months; has been in the habit of drinking beer freely, but has not been intemperate. For two weeks there has been pronounced jaundice, anorexia, and bilious vomiting soon after eating; dizziness, flatulence, occasional diarrhea, with pain at epigastrium; slight edema of feet and ankles. These symptoms have been increasing. There has been no headache and no hemorrhages or chills. The tongue was clean, the pulse 80, temperature 97.8°. The heart and lungs were normal. The liver was much enlarged and smooth. The spleen was felt below the ribs. There was no ascites. The urine had a sp. gr. of 1017, was of a deep yellow color, and contained a trace of albumen and much bile; sediment normal. The blood was negative.

PATHOLOGY.

1. Name the system diseases of the afferent or sensory nervous system.
2. How is malaria propagated?
3. Enumerate the causes of sudden death in children.
4. What is the pathology of diabetes?
5. Describe the bacillus of diphtheria.
6. What are the causes of fatty liver?
7. Describe the blood in leucemia.
8. Discuss the relationship between arterial disease and chronic nephritis.
9. What are the microscopic findings of simple chronic gastritis?
10. Define: Vaccine, opsonin, bacterin, agglutinin, lysin.

OBSTETRICS.

1. Give the various diameters of the inlet and outlet of the pelvis.
2. Give a good description of the anatomy of the uterus.
3. What are the different stages of labor? Describe each.
4. Give the various diameters of the fetal head.
5. Describe the sutures, fontanelles, and protuberances of the fetal head.
6. What is the mechanism of delivery in the R. O. P. position?
7. What are the indications and contraindications for the use of the obstetric forceps?
8. Give the indications for the induction of premature labor and describe the best method.
9. What is post-partum hemorrhage? How prevented?
10. What is puerperal sepsis? Give treatment.

SURGERY.

1. Give the symptoms and prognosis of fracture of the olecranon process of the ulna.
2. Give the causes of non-union of fractures.
3. Give the causes and symptoms of compression of the brain.
4. Describe the different forms of dislocation of the shoulder-joint, and state which is the most frequent.
5. Give the symptoms and diagnosis of tuberculosis of the knee-joint.
6. Give the symptoms and diagnosis of hydrocele.
7. Give symptoms and diagnosis of stone in the common duct.
8. Give some of the causes of vesical hemorrhage.
9. Describe acute osteomyelitis.
10. What are the early symptoms of carcinoma of the breast?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

October 5, 1909.

ANATOMY.

1. The *clavicle* forms the anterior part of the shoulder girdle; it articulates internally with the first part of the sternum, and externally with the acromion process of the scapula. It is broad and flattened at its outer end, and thick and rounded at the inner end. It consists of a double curve, the outer part is concave forward, the inner part convex forward. The bone has two surfaces, superior and inferior; and two borders, anterior and posterior. On the under surface are the conoid tubercle, a groove for the subclavius, a rough impression for the rhomboid ligament. *Muscles attached to it* are: Deltoid, trapezius, pectoralis major, subclavius, sternomastoid, and sternohyoid. *Ligaments attached to it* are: Interclavicular, rhomboid, conoid, trapezoid, and capsular (of sternoclavicular and acromioclavicular articulations).

2. *Muscles attached to the tibia* are: Semimembranosus, semitendinosus, biceps, gracilis, sartorius, tibialis anticus, extensor longus digitorum, tibialis posticus, soleus, popliteus, flexor longus digitorum, quadriceps extensor.

3. The *hip-joint* is an enarthrodial joint, formed by the head of the femur and the acetabulum. The articular surfaces are covered with cartilage. Near the center of the head of the femur is attached the ligamentum teres. The *ligaments* are: (1) The capsular, which embraces the margin of the acetabulum above, and the neck of the femur below. (2) The ileofemoral or Y ligament,, which passes obliquely across the front of the joint, and is attached above to the anterior inferior spine of the ileum, and below to the anterior intertrochanteric line. (3) The ligamentum teres. (4) The cotyloid ligament, which deepens the acetabulum, and bridges over the cotyloid notch, being there called (5) the transverse ligament. The joint has a very extensive synovial membrane. It is capable of the following movements: Flexion, extension, abduction, adduction, circumduction, and rotation.

4. THE POPLITEAL SPACE is *bounded: Above, and externally* by the Biceps; *above, and internally* by the Semimembranosus and Semitendinosus; *below, and externally* by the Plantaris and external head of the Gastrocnemius; *below, and internally* by the inner head of the Gastrocnemius.

Contents: Popliteal vessels with branches, external saphenous vein, external and internal popliteal nerves, small sciatic nerve, lymphatic glands, and loose areolar tissue.

5. SARTORIUS. *Origin:* Anterior superior spine of ilium, and part of notch below. *Insertion:* Inner side of tibia near tubercle. *Nerve supply:* Middle cutaneous, or branch from anterior crural.

TRICEPS: The long, or middle, head arises from a depression on the axillary border of the scapula immediately below the glenoid cavity; the external head from the root of the great tuberosity on the posterior surface of the humerus, and the upper part of the musculospiral groove; the internal head from the posterior surface of shaft of humerus, below musculospiral groove, and the internal and external muscular septa. It is inserted into the back part of the upper surface of the olecranon process of the ulna. *Nerve supply:* Musculospiral.

GASTROCNEMIUS: The inner head arises from a depression on the upper and back part of the inner condyle of the femur and the adjacent part of the femur; the outer head from an impression on the external surface of the outer condyle, and from the posterior surface of the femur immediately above the condyle. It unites with the tendon of the soleus to form the tendo Achillis, which is inserted into the lower part of the posterior surface of the os calcis. *Nerve supply:* Internal popliteal.

PECTORALIS MAJOR. *Origin:* Anterior surface of inner half of clavicle, anterior surface of sternum, from the cartilages of the second to sixth ribs, and from the aponeurosis of the external oblique of the abdomen. *Insertion:* Into the outer bicipital ridge of the humerus. *Nerve supply:* External and internal anterior thoracic.

PECTORALIS MINOR. *Origin:* From third and fourth and fifth ribs, just external to the cartilages, and from aponeurosis over intercostal muscles. *Insertion:* Into coracoid process of scapula. *Nerve supply:* Internal anterior thoracic.

6. A line from the lower border of the second left costal cartilage (one inch from sternum) to upper border of third right costal cartilage represents the *base line;* the

right side will be a line drawn from right side of upper limit to seventh right chondrosternal articulation; the *lower limit* is a line from this last point to the apex (in fifth intercostal space, three and one-half inches from midline); the *left side,* from left end of upper border to left of apex. The valves are: Aortic, mitral, tricuspid, pulmonary (and Eustachian and coronary).

7. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius. The *branches* are: (1) Above the clavicle; communicating, muscular, posterior thoracic, and suprascapular. (2) *From outer cord:* External anterior thoracic, musculocutaneous, and outer head of median. (3) *From inner cord:* Internal anterior thoracic, lesser internal cutaneous, ulnar, and inner head of median. (4) *From posterior cord:* Subscapular, circumflex, and musculospiral.

8. The *diaphragm* is a musculofibrous septum which divides the thoracic from the abdominal cavity; it is fan-shaped; the broad, eliptical portion is horizontal, and the crura are vertical. It is attached to the ensiform, to the internal surfaces of the lower six costal cartilages, to bodies and intervertebral substances of first, second, and third lumbar vertebræ. Its *openings* are: (1) The aortic, transmitting the aorta, vena azygos major, and the thoracic duct; (2) the esophageal, transmitting the esophagus, pneumogastric nerves, and some small esophageal arteries; (3) the opening for the vena cava, transmitting the inferior vena cava, and small branches of the right phrenic nerve; (4) the right crural, transmitting the right splanchnic nerves; (5) the left crural, transmitting the left splanchnic nerves and the vena azygos minor.

9. Relations of prostate. *Anteriorly:* Symphysis pubis, anterior ligaments of bladder, branches of dorsal vein of penis. *Posteriorly:* Rectum. *Laterally:* Levator ani. *Base:* Surrounds neck of bladder, seminal vesicles, and vasa deferentia. The *apex* rests on triangular ligament.

10. At middle of thigh would be cut: Skin; fascia; muscles, adductor longus, sartorius, gracilis, rectus femoris, adductor brevis, adductor magnus, semimembranosus, semitendinosus, vastus internus, crureus, vastus externus, biceps; vessels: profunda, femoral, external circumflex, internal saphenous vein; nerves: external cutaneous, superficial obturator, anterior crural, sciatic, small sciatic; bone: femur.

PHYSIOLOGY.

1. *Physical properties of blood:* Fluid, somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100° F.). *Functions:* For red and white corpuscles, see Question 2.

Plasm conveys nutriment to the tissue; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

2. (*a*) Red Corpuscles. *Origin:* From red marrow of bones (and during fetal life from spleen, liver, and connective tissue cells). *Function:* To carry oxygen from the lungs to the tissues. *Number:* About 4,500,000 to 5,000,000 per cubic millimeter.

(*b*) White Corpuscles. *Origin:* From spleen, lymphatic glands, and lymphoid tissue. *Classification:* (1) Small mononuclears; (2) large mononuclears; (3) transitionals; (4) polynuclears; (5) eosinophiles; and (6) mast cells. *Function:* (1) To serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma. *Number:* Normally between 7,000 and 10,000 or 12,000 in each cubic millimeter of blood.

3. *The forces concerned in the circulation of the blood* are: The force and frequency of the contractions of the heart, the elasticity and tone of the arterial walls, the resistance in the capillaries and tissues, the valves in the veins, the contraction of the muscles, the aspiration of the thorax.

4. Lymph is a colorless, albuminous fluid, alkaline in reaction, specific gravity of about 1015. *Function:* (1) It conveys nutriment to all cells not directly reached by the blood; (2) in the intestines, it absorbs nutrient material (chiefly fat) and pours it into the blood stream for distribution; (3) it takes certain waste matters to the blood to be later eliminated by the lungs, kidneys, and skin.

5. *Respiration* is the act by which air is taken into and expelled from the lungs. *Function:* (1) To introduce oxygen into the system; (2) to excrete carbon dioxide. It is performed by inspiration and expiration.

6.

DIGESTIVE FERMENTS	ORIGIN	FUNCTION
Ptyalin.	Saliva.	Changes starches into dextrin and sugar.
Pepsin.	Gastric juice.	Changes proteids into proteoses and peptones in an acid medium.
Trypsin.	Pancreatic juice.	Changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; in an alkaline medium.
Amylopsin.		Converts starches into maltose.
Steapsin.		Emulsifies and saponifies fats.
Invertin.	Intestinal juice.	Converts maltose into glucose.

7. *The organs of elimination* are: (1) *Skin,* for sweat (urea, water, salts); (2) *lungs* (for carbon dioxide, water); (3) *kidneys,* for urine (water, urea, salts), and (4) *intestines* (feces).

8. (*a*) *The functions of the liver* are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

(*b*) *The function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

(*c*) *The function of the thyroid* is not definitely settled; (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

9. I. Olfactory. *Distributed* to the Schneiderian membrane of nose. *Function,* sense of smell.

II. Optic. *Distributed* to retina. *Function,* sense of sight.

III. Motor oculi. *Distributed to:* Superior rectus, inferior rectus, internal rectus, inferior oblique, and levator palpebrarum muscles. *Function,* motor to these muscles.

IV. Trochlear. *Distributed* to superior oblique muscle. *Function,* motor to this muscle.

V. Trifacial. *First, or ophthalmic branch,* supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal gland, and skin of nose. *Second, or superior maxillary branch,* supplies sensation to skin and conjunctiva of lower eyelid, nose, cheek, upper lip, upper teeth, and palate. *Third, or inferior maxillary branch,* supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, and skin of lower part of face. This branch, in addition, supplies motion to the muscles of mastication (Masseter, temporal, external, and internal pterygoids), and the mylohyoid and anterior belly of the digastric.

10. *The vasomotor nervous system* consists of a center in the medulla, subsidiary centers in the spinal cord and vasomotor nerves. The nerves are: (1) Vasodilator (which increase the caliber of the arterioles), and (2) vasoconstrictors (which diminish the caliber of the arterioles). *Functions:* (1) To dilate arterioles; (2) to constrict arterioles; (3) to maintain tonicity of blood vessels; (4) to maintain peripheral resistance; (5) to regulate the amount of blood supplied to a part.

CHEMISTRY.

1. The glucose in the urine reduces the cupric sulphate of Fehling's solution to copper oxide.

2. Add a small amount of solution of nitrate of silver; in the presence of chlorides there will be a white precipitate insoluble in dilute HNO_3, but soluble in dilute NH_3.

3. Hydrochloric acid, pepsin, proteoses, peptones, etc. The relative and absolute amounts will necessarily vary according to the kind and quantity of food ingested.

4. Nitrites in drinking water denote contamination by sewage.

5. *Normal urine* consists of: Water, 95 per cent.; solids, 5 per cent. The latter are: Urea, 2.8 per cent.; uric acid, 0.06 per cent.; hippuric acid, 0.03 per cent.; creatinin, 0.06 per cent.; extractives, 0.8 per cent.; sodium chloride, 0.8 per cent.; phosphates, 0.2 per cent.; sulphates, 0.1 per cent.; oxides of calcium, magnesium, sodium, and potassium, 0.1 per cent.

6. Ammonium acetate is formed.

7. Calculi are composed of: (1) Most frequently, uric acid, sodium or ammonium urate, calcium oxalate, calcium phosphate, and ammonio-magnesium phosphate. (2) More rarely, cystin, xanthin, potassium or magnesium or calcium urate, and calcium carbonate.

8. About 8 per cent.

9. Trichloracetic acid, salicyl-sulphonic acid, picric acid, potassium ferrocyanide, Spiegler's test, Tanret's test, Jolle's reagent.

10. *A base* is a ternary compound capable of entering into double decomposition with an acid and producing a salt and water.

An acid is a compound of an electro-negative element or radicle with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element without the formation of a base.

An alkali is a substance which is basic in character, alkaline in reaction, is caustic in action, and can saponify fats.

An alcohol is the hydroxide of a hydrocarbon radicle.

An ether is the oxide of a hydrocarbon radicle.

TOXICOLOGY.

1. *Toxicology* is that branch of medical science which appertains to poisons; it includes their character, origin, actions, symptoms produced, antidotes, treatment, and detection.

2. Overdose of chloroform. *Symptoms:* I. Flushed face, contracted pupils, rapid and full pulse. II. Slow respiration, lowered temperature, dilated pupils, relaxed muscles, slow and full pulse. III. Irregular pulse, superficial respiration, dilated pupils, blue skin and lips, stertorous breathing, skin cool and covered with perspiration. *Treatment:* If the chloroform has been swallowed: Wash out the stomach, keep the patient warm, give hypodermic of strychnine. If during inhalation, stop further administration, start artificial respiration, give oxygen, and faradic current.

3. *Post-mortem appearances:* Cerebral and meningeal vessels are engorged; the lungs, liver, and kidneys are congested; the blood is dark and fluid; if the chloroform has been swallowed, the mucous membrane of mouth, stomach, and intestines is inflamed. The odor of chloroform may be present.

4. *Symptoms of poisoning by oxalic acid:* "The sour taste of the acid is rapidly followed by a burning pain, increasing in intensity, in the mouth, throat, and stomach, and persistent vomiting of a dark, 'coffee-ground' material. The pulse becomes small and imperceptible, and the patient dies in collapse, preceded frequently by convulsions, within half an hour. If the case be prolonged, swallowing becomes very difficult and painful; there are numbness and tingling of the skin; twitchings of the facial muscles; convulsions, frequently tetanic; delirium, and lumbar pain. Death occurs in some cases within three to ten minutes, sometimes almost immediately, and in some cases it is delayed for several days."

Treatment: "Magnesia (magnesia usta) or slaked lime suspended in a small quantity of water, or mucilaginous liquid, should be given *as soon as possible*. If vomiting do not occur, and if the symptoms of corrosion be not marked, an emetic. The stomach pump should *not* be used, nor should the alkaline carbonates be depended upon as antidotes."

5. *Post-mortem appearances:* The mucous membrane of mouth, esophagus, and stomach is whitish, easily detached, and looks as if it had been scalded; the muscular coat is red and thick; the stomach contains a pultaceous material, acid, and like "coffee ground" vomitus; the kidneys may show crystals of calcium oxalate; the urine may contain oxalates.

6. The *symptoms of acute lead poisoning* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms."

The *treatment* consists in administering "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube."

7. *Post-mortem appearances:* Not always characteristic; mucous membrane of stomach may be red or gray; there is a blue line on the gums; the colon may be constricted.

8. *Signs of death by drowning:* Froth at nostrils and mouth; pallor and goose skin; maceration of epidermis of palms of hands and soles of feet; sand or mud may be under the nails or in the hands; water and foreign matter are generally in the stomach and also in bronchi; lungs are swollen and emphysematous; the right side of the heart is engorged and the left side is empty; the liver is engorged.

9. *Symptoms of asphyxiation by charcoal vapor:* Headache, drowsiness, vertigo, tinnitus aurium, vomiting, dyspnea, pain and oppression in chest, irregular heart, stertorous breathing.

10. *Post-mortem appearances:* The blood is of a bright red color and the skin shows bright reddish spots on face, chest, and abdomen; the brain is congested; all the internal organs are colored by the bright red blood.

SYMPTOMATOLOGY.

1. *Pseudoleukemia* is a disease characterized by hyperplasia of the lymphatic glands and progressive anemia; there is no great excess of white corpuscles. It is also known as Hodgkin's disease. *Symptoms:* Glands of neck, axilla, and groin are enlarged; anemia is present; the swellings are painless and do not, as a rule, suppurate; dyspnea may ensue; spleen and thyroid are apt to become enlarged; palpitation, shortness of breath, and hemic murmurs may be found. *Prognosis* is unfavorable; recovery is rare; cases may last from six months to three or four years.

2. Bronchopneumonia and capillary bronchitis are the same.

LOBAR PNEUMONIA	BRONCHOPNEUMONIA
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

3. *Exophthalmic goiter* is a disease characterized by: Exophthalmos, enlarged thyroid, tachycardia, and tremors. The *principal symptoms* are the four just mentioned, with sometimes anemia, fever, emaciation, diarrhea, pigmentation, and profuse perspiration.

4. TABES DORSALIS. *Etiology:* Tabes dorsalis is a disease of adult life; is more common in men than in women; is more common in cities than in the country; syphilis is believed to be the most frequent direct cause; alcoholism, injury, exposure to cold and wet, have all been urged as causes, but they are not now assigned so important a place as etiological factors as was formerly the case.

Symptoms: Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil.

Prognosis: The disease is probably never cured; it may be arrested, and some of the symptoms may be ameliorated. It may last from four to twenty years.

5. *Icterus may be caused by:* Catarrh of the duodenum and common bile duct, pancreatic disease, gallstones, cirrhosis of the liver, obstruction of the bile ducts, septicemia.

acute yellow atrophy of the liver, tumors of liver, pancreas, stomach, or kidney, certain infections and poisons.

6. Diabetes mellitus and diabetes insipidus.

In *diabetes mellitus* the urine has a high specific gravity and contains glucose; complications are many and frequent.

In *diabetes insipidus* the urine has a low specific gravity and does not contain glucose; complications are rare.

7. *Variola* is an acute infectious and contagious disease, of unknown origin, and characterized by rapid onset and fever, pains in head and back, and a rash which appears on the third or fourth day and passes through the stages of macule, papule, vesicle, and pustule.

For description of the stages of the disease, see French's "Practice of Medicine" (1907), pages 301 *et seq.*, or Osler's "Practice of Medicine" (1909), pages 115 *et seq.*

8. The *exanthematous diseases of children* are: Variola, varicella, scarlet fever, measles, and German measles.

Variola: The eruption usually appears first on the forehead and wrists, and on the third or four day; it is first macular, then papular, then vesicular, and, finally, pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin. *Varicella:* The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; deesquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type; the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent. *Measles:* Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small, dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present. *German measles:* Period of incubation, ten to seventeen days. Stage of invasion, one day. Eruption appears on first day, is most intense on second day, consists of red papules, often fades from face before it is seen on the limbs. The pulse is not much accelerated, all the symptoms are slight. Desquamation is very slight. There may be slight sore throat and swollen cervical glands. Koplik's spots are absent.

9. The *different forms of nephritis* are: (1) Acute parenchymatous; (2) chronic parenchymatous; (3) chronic interstitial. The following table is from Gould & Pyle's Cyclopedia:

ACUTE PARENCHYMATOUS NEPHRITIS	CHRONIC PARENCHYMATOUS NEPHRITIS	CHRONIC INTERSTITIAL NEPHRITIS
1. Most common in children, from exposure or infectious fevers.	1. Later life; often the consequence of acute attack.	1. Late life; often results from alcoholism, gout, lead poisoning.
2. Edema of lower eyelids; then of upper extremities, trunk, and, lastly, lower extremities.	2. In early stage same as acute form; later, dropsy may diminish.	2. Dropsy slight or entirely absent.
3. Urine scanty, dark or smoky color, high specific gravity, 1025 or over.	3. Urine normal or increased amount; specific gravity may fall to 1010; urine pale.	3. Urine greatly increased; specific gravity low, 1005; urine pale in color.
4. Large amount of albumin.	4. Late in attack, greatly diminished; occasionally absent.	4. Albumin greatly diminished, often absent.
5. Variety of casts, such as hyaline, blood, epithelial, and waxy casts, also free red blood globules, and epithelial cells.	5. Large and small granular casts; compound granule cells, and fatty epithelium.	5. Hyaline or finely granular casts, occasionally dark in color; infrequently blood casts and oil droplets.
6. Urea diminished.	6. Urea diminished.	6. Urea diminished.
7. Recoveries frequent.	7. Recoveries rare.	7. Indefinite duration, but never cured.

10. "Gallstone in the common duct is possible, but unlikely, owing to the presence of splenic tumor, the lack of any intermission in the symptoms, and the absence of pain, fever, or chills. Catarrhal jaundice cannot be excluded, though it rarely leads to much enlargement of the liver or spleen. The points against cancer are the absence of pain, cachexia, or irregularities on the liver surface. Syphilis might produce all these symptoms, and can be positively excluded only by the therapeutic test. Cirrhosis, or the combination of cirrhosis and fatty infiltration, is the most likely diagnosis. This accounts better than any other hypothesis for the splenic enlargement, the large, smooth liver, and the jaundice. The gastric symptoms would then result from passive congestion of the stomach. The course of the case confirmed the diagnosis of cirrhosis."—(Cabot's *Case Teaching in Medicine,* from which the question is taken.)

PATHOLOGY.

1. Locomotor ataxia; general paralysis of the insane; herpes zoster.

2. Malaria is propagated by the bite of a mosquito (anopheles), which harbors the plasmodium malariæ.

3. *Causes of sudden death in children:* Asphyxia, malformations, status lymphaticus, atelectasis, marasmus, internal hemorrrhages, convulsions, and heart failure after diphtheria.

4. For *pathology of diabetes,* see French's "Practice of Medicine" (1907), pages 935 *et seq.;* or Osler's "Practice of Medicine" (1909), pages 412 *et seq.*

5. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

6. The *causes of fatty liver* are: Anemia, phthisis, cachetic conditions, obesity, phosphorus poisoning, pulmonary diseases, infectious diseases (as yellow fever, pyemia).

7. In *leukemia* the *blood* is light in color, specific gravity is lowered, coagulation is slow, the white corpuscles are much increased in number (there may be from 150,000 to 500,000 per c. mm., or even more); myelocytes are present in large numbers in the splenomedullary type; red cells may be moderately diminished, and some may be nucleated.

8. Chronic nephritis is often secondary to arteriosclerosis; in other cases the arteries are sclerotic even if there is no causal relation between the two conditions; sometimes it is hard to say which condition was primary. In many cases one or more of the coats of the arteries are thickened; this thickening is not evenly distributed, and is apt to be most marked in the renal vessels. Aneurysm, atheromatous or hyaline changes are often present in the blood-vessels in nephritis.

9. In *simple chronic gastritis,* the cells of the glands are eroded, or atrophied, or show cloudy swelling; round cell infiltration is present in the tubules; the glands are dilated and filled with an exudate and desquamated cells; new connective tissue forms between the glands.

10. *Vaccine* is an attenuated virus which, when introduced into the body of an animal, enables it to withstand the development of an infectious disease. *Opsonin* is that quality of a serum which makes a microorganism more susceptible to phagocytosis. *Bacterin* "is a preparation of killed bacteria suspended in normal solution which is injected for the purpose of raising the opsonic index of patients suffering from infection by that organism. *Agglutinin* is something in the blood serum of an animal affected with a bacterial disease which is capable of causing the clumping of the bacteria which caused the disease. *Lysins* are bacterial products which are capable of destroying alexins, and so promote the growth of the bacteria.

OBSTETRICS.

1. The pelvic diameters:

	Anterio-posterior.	Oblique.	Transverse.
Inlet	4 inches.	4½ inches.	5 inches.
Outlet	5 inches.	4½ inches.	4 inches.

2. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, and rectouterine.

The arteries are the uterine and ovarian; the nerves are from the uterovaginal plexus, the hypogastric plexus, and the vesical plexus.

3. Labor is divided into three stages: The *first stage* begins with the commencement of labor and ends with the complete dilatation of the os uteri. The *second stage* begins with the complete dilatation of the os uteri and ends with the birth of the child. The *third stage* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

For description of each, see Williams' "Obstetrics" (1909), pages 226 *et seq.*; or Hirst's "Obstetrics" (1909), pages 317 *et seq.*

4. The fetal head has the following diameters: Occipitofrontal, occipitomental, bitemporal, biparietal, suboccipitobregmatic, trachelobregmatic, and mentobregmatic. Of these, the occipitofrontal is 4½ inches, the occipitomental is 5½ inches, and all the others are approximately 3½ inches.

5. See Williams' "Obstetrics" (1909), page 152.

6. See Williams' "Obstetrics" (1909), pages 267 *et seq.*; or Hirst's "Obstetrics" (1909), page 404.

7. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior; (*b*) mentoanterior face; (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapse funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both.

Contraindications for the use of the forceps are: Mechanical obstruction of any nature in the parturient canal; incomplete dilatation of the os; non-rupture of membranes; non-engagement of the presenting part; the fact that the fetal head is either too large or too small; distended bladder or rectum.

8. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) the presence of a hydatidiform mole; (7) habitually large fetal head.

The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of a soft rubber bougie into the uterus; (5) intrauterine injection of glycerin, water, or some other fluid. For description of method, see Williams' "Obstetrics" (1909), pages 381 *et seq.*; or Hirst's "Obstetrics" (1909), page 799.

9. Postpartum hemorrhage is hemorrhage from the parturient canal occurring after the birth of the child; it may occur immediately after the birth of the child, or at any time within several hours.

Prevention: Exert gentle pressure on the fundus of the uterus during birth of fetus and secundines; prevent too rapid delivery; after birth of head, give a dram of fluid extract of ergot; after complete delivery, give vaginal douche of creolin and water, and apply a uterine pad (externally) and abdominal binder; the patient should be kept quiet, both mentally and physically.

10. *Puerperal sepsis* is a condition beginning within a week after labor, generally about the third or fourth day, and characterized by fever, inflammation of one or more of the reproductive organs, and general septic infection. For treatment, see Williams' "Obstetrics" (1909), pages 883, *et seq.*; or Hirst's "Obstetrics" (1909), pages 732, 737, *et seq.*

SURGERY.

1. *Symptoms of fracture of the olecranon process of the ulna* are: The upper fragment is drawn upward; swelling; the forearm is partly flexed and cannot be extended readily; flexion of elbow increases the distance between the fragments; crepitation is present. The *prognosis* is fair, fibrous union is common, and ankylosis, or joint stiffness may occur.

2. *Causes of non-union of fractures:* Ill health, want of approximation of the ends of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility.

3. *Causes of compression of brain:* Hemorrhages, abscess, tumor, depressed fractures, edema, new growths of bone. *Symptoms:* Unconsciousness, slow and stertorous breathing, full and slow pulse, later becoming rapid, temperature raised, pupils unequal and fixed, hemiplegia, sphincters paralyzed, reflexes increased on paralyzed side.

4. The *various dislocations of the shoulder-joint* are: (1) Subcoracoid—forward, inward, and downward. (2) Subglenoid—downward, forward, and inward. (3) Subspinous—backward, inward, and downward. (4) Subclavicular—forward, inward, and upward.

The *special diagnostic signs* are:

(1) *Subcoracoid:* The head of the humerus is felt below the outer end of the clavicle; there is little or no shortening of the limb; the elbow is directed outward and backward.

(2) *Subglenoid:* The head of the humerus can be felt in the axilla; the arm is decidedly lengthened; the elbow is flexed, and there are signs of pressure on vessels and nerves.

(3) *Subspinous:* The head of the humerus is felt below the acromion process and behind; the arm is rotated inward and the elbow is displaced outward.

(4) *Subclavicular:* The head of the humerus is felt below the clavicle; the elbow is far from the side, and the limb may be shortened.

The most frequent of these dislocations of the shoulder joint is the subcoracoid.

5. In *tuberculosis of the knee-joint* there are: Swelling at sides of and above patella; joint is semiflexed; skin is edematous; there is a doughy feel round patella; foot is everted, muscles of thigh and calf are wasted; pain is variable; tibia displaced outward and backward, is flexed and externally rotated; the limb shortened; abscesses may form.

6. *Hydrocele* is diagnosed by its *translucency*. Further, it is a tumor which grows from below upward, is tense and fluctuating, is generally situated in front of the testicle, and gives no impulse on coughing.

7. *Stone in the common duct* is characterized by: Jaundice, colic, clay-colored stools, collapse, nausea, vomiting; the liver is enlarged and tender, and the gall-bladder is shrunken.

8. *Causes of vesical hemorrhage:* Traumatism, stone, inflammation, tumors, tuberculosis, and filaria.

9. *Acute osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of the bone. It is *caused* by infection, the bacteria gaining entrance either through a wound or by extension from neighboring tissues, or they may be brought by the blood. *Pathological changes:* "The area of the medulla affected becomes hyperemic; exudation occurs in the cancellous spaces, Haversian canals, and under the periosteum. Pus soon forms in these three situations. If the disease begins in the superficial part of the bone the pus may only be subperiosteal, the deeper part of the bone escaping, though large areas of the superficial portion may die from the combined action of (1) stripping up of the periosteum by the pus; (2) strangulation of the vessels in the bone by the pressure of the exudation, and (3) the toxic action of the bacterial products. . . . When the disease begins in the deeper layers of the bone the pus may reach the periosteum, or extend along the medullary cavity, so that the veins become filled with septic thrombus, which may be disintegrated and carried off as septic emboli (pyemia). There is profound toxemia, and necrosis of the whole diaphysis may occur. . . . If the infection is mild, a chronic abscess may be formed in the cancellous tissue. The usual course of an acute case, if a patient survives, is that there is some necrosis of the shaft of the bone. The abscess bursts externally, and there are numerous openings in the skin leading through openings (cloacæ) in the periosteum and involucrum down to the sequestrum. The sequestrum becomes loose in six weeks to six months. *Symptoms:* Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present. It is to be *diagnosed* from three conditions: (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tubular arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis*, in which the bone and periosteum are not affected, and in which there is always a wound.

10. *Early symptoms of carcinoma of breast:* Hard nodule, painless, fixed to gland, slowly but steadily increases in size; later it becomes harder and is fixed to skin; the skin is dimpled and may ulcerate; the nipple may be retracted; pain is present, and the breast cannot be freely moved.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H Sanders, Montgomery.	Montgomery	Jan. 11
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 3
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 10
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 5
Colorado	S. D. Van Meter, 1723 Fremont Street, Denver	Denver	Jan. 4
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Mar. 8
Delaware	J. H. Wilson, Dover	Dover	June 21
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	Jan. 11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	April 4
Georgia	E. R. Anthony, Griffin	Atlanta	April —
Idaho*	W. F. Howard, Pocatello		April 5
Illinois	J. A Egan, Springfield	Chicago	Jan. —
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 11
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	F. P. Hatfield, Olathe	Topeka	Feb. 8
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 17
Maine	F. W Searle, Portland	Portland	Mar. 8

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Arkansas.—The new law regulating the practice of medicine in this State makes provision for reciprocity.

Mississippi.—Out of eighty-one applicants at the recent examination, only 21 were licensed to practice medicine.

Pennsylvania.—In the last examination there were 354 candidates; of these only 20 failed, or 5.6 per cent. As a rule there are about 14 per cent. of failures in the June examinations.

Technique of the Conservative Cesarean Section.—J. A. Doleris advocates absolute asepsis in all obstetric operations, just as we use it in gynecology. The genitalia as far up as can be reached into the cervix should be made antiseptic by the use of pure tincture of iodine. This is especially important in carrying out the conservative cesarean section. The time for the operation should be selected beforehand, at about the expected end of pregnancy, and the details of the operation carried out at leisure. The author uses surgical disinfection of the genitals and the operative zone, a short incision without exteriorization of the uterus, manual compression of the pedicles, ergot hypodermic injections for hemorrhage, suture with choromatized gut, vaginouteral drainage with gauze, and abdominoperitoneal drainage. His statistics of eleven cesarean sections done during the past year show eleven living infants, and only one death among the mothers. This death was in a case which had been in labor for 55 hours, with dilated cervix and amniotic fluid draining away. She died of sepsis and adynamia.—*La Gynécologie.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of December 11, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	564	177
Diphtheria	366	45
Measles	385	9
Scarlet Fever	337	14
Smallpox	—	—
Varicella	111	—
Typhoid Fever	59	11
Whooping Cough	120	5
Cerebrospinal Meningitis	1	4
Malarial Fever	—	—
Totals	1,943	265

Bacteriological Examination of the Normal Lochia.—Ercole Cova has made a bacteriological examination of the lochia in twenty cases of normal puerperal women, all cases that had any rise of temperature being excluded. He found that the cavity of the uterus is absolutely sterile, while the germs are habitually found in the vagina. For the first twenty-four hours the lochia are perfectly sterile. After that time germs may appear in it, probably coming from some that were concealed in the crypts and sulci of the mucous membrane. There are more germs found in the vulva than in the vagina, some of them coming from within, some from without. The vaginal flora consist of various forms of cocci, especially diplococci, and are simply saprophytic and not virulent. The colon bacillus is easily demonstrated, and may enter the vagina.—*Folia Gynæcologica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 3, 1909:

RESULTS ACHIEVED BY THE MOVEMENT FOR SANITARY AND MORAL PROPHYLAXIS—OUTLOOK FOR THE FUTURE.*

BY PRINCE A. MORROW, M.D.

NEW YORK.

IN a paper before this society two years ago, I presented a résumé of the results accomplished by the movement for sanitary and moral prophylaxis in this country. In entering upon the duties of this office for a third presidential term, the occasion seems fitting for a review of the results achieved by this work during the past two years. Such a retrospect, it is believed, will be found to afford substantial evidences of real progress, and may serve as a stimulus for more active efforts in the future. Moreover, this experimental work furnishes a valuable basis for the study of the most practical lines along which this work may be effectively directed.

First, as to the growth of this movement. The most obvious evidence of this growth is the multiplication of societies which have undertaken this work in different parts of this country. From a handful of half-hearted men who met in this hall some four and a half years ago to discuss the wisdom and expediency of forming a society for the study and prevention of a class of diseases growing out of the social evil, the parent society has steadily grown in numbers, strength, and influence, and the movement has spread to many other states and cities. Branch societies, or societies with similar aims and purposes, have been organized in Philadelphia, Baltimore, Chicago, Milwaukee, Indiana, St. Louis, Denver, Portland, Spokane, California, West Virginia, Jacksonville, and the City of Mexico. Societies are in process of formation in Georgia, Connecticut, Texas, New Jersey, and other states.

Some four weeks ago I addressed a letter to the secretaries of these several societies asking for details of their organization and a résumé of their work. I propose to lay before you this evening a brief report embodying the results of these inquiries. The secretaries of the Pennsylvania Society and the Maryland Society have kindly consented to report the work of their respective societies.

The keynote of this movement was sounded as a campaign of education, and while these various organizations have acted independently, the work of all has been chiefly directed along educational lines and is to a certain extent homogeneous.

As this movement was inaugurated by the formation of the American Society of Sanitary and Moral Prophylaxis in this city, February, 1905, it is proper that this report should begin with a summary of its work.

The educational work of this society has been attempted in three directions: 1. By public meetings and conferences. 2. By the circulation of educational literature and pamphlets. 3. By lectures.

This society, I believe, was the first organization to hold meetings in this hall for the discussion of medical topics to which the public was invited. It certainly has the credit of lifting the taboo from a class of diseases, the discussion of which had always been behind closed doors. It had the courage to bring the discussion of these diseases into the open, to pronounce their names before a public audience, and to place them on the same plane of publicity as other infectious diseases dangerous to the public health. The papers and discussions at these meetings appear in the published transactions of the society. In addition to the first pamphlet issued by the society, 5000 copies of which were distributed, several thousand copies of reprints from *Charities and Commons*, a symposium on the treatment of venereal diseases, and more recently, a symposium on blindness of the newborn, it has issued five educational pamphlets: (1) "The Young Man's Problem," (2) "Education in the Physiology and Hygiene of Sex for Teachers." (3) "The Relations of Social Diseases with Marriage," (4) "The Boy Problem," (5) "How My Uncle, the Doctor, Instructed Me in Matters of Sex," intended for parents who feel themselves incompetent to instruct their children.

The fact that there was a demand for a third edition of Pamphlet No. 1 (the eighteenth thousand) within two years; for a second edition of No. 3 (the twelfth thousand) within a year, and that this demand comes from parents and educators, shows a remarkable receptivity on the part of the public for sound and scientific sex instruction. It is believed that the character of the educational literature of this society, which is everywhere spoken of as sane, dignified, and at the same time clean and free from mawkish sentiment, has contributed to establish the high repute in which this society's work is held.

In addition, numerous addresses before state medical associations, state conferences of charities, federations of women's clubs, sociological, and other associations, which have been widely circulated through the journals in which they were published, have contributed largely to the creation of a sentiment in favor of this work on the part of both the medical profession and the public.

When the lecture work of the society was inaugurated three years ago it was difficult to secure audiences or opportunities. The Committee on Lectures knocked at many doors which refused to open. During the first year only twenty-five lectures were

*Read at a meeting of the American Society of Sanitary and Moral Prophylaxis, October 14, 1909.

given. Within the last two years, since the value and importance of this work has been more generally recognized, over two hundred lectures have been given, and numerous requests for lectures could not be granted owing to the lack of necessary funds. I have here something over a hundred letters, most of them from the principals of the associations, schools, or groups in which the lectures were given, testifying to the favorable impression they made and the high appreciation with which they were regarded, and in many cases asking that they be repeated.

Lectures have been given in high schools, colleges, Young Men's Christian Associations, the settlements, the industrial alliance, boys' clubs, young women's clubs, employees' associations, and before various social groups. One of the most valuable fields of lecture work comes through the Public Education Association connected with the public schools. "These lectures before parents," writes the Executive Committee of this association, "were very helpful and showed plainly that they answered a great need. If people realized how much good could be done in this way they would be willing to contribute funds to make it possible to have a series of such lectures in every school in this city." Certain phases of this society's work will be again alluded to.

The Chicago Society, organized in October, 1906, has been most active and energetic in the preparation and circulation of leaflets which are distributed gratuitously or at a nominal price. Two years ago this society reported that 5000 copies of an educational pamphlet had been published, and ninety thousand copies of a leaflet entitled "Sexual Hygiene," for young men, had been circulated. Since then, two official circulars, one on family protection and another on community protection, have been issued. "Over 400,000 copies of these circulars have been distributed, and it is thought they will soon reach the half million mark. The circulation of these leaflets has brought the society into communication with over 600 universities, Young Men's Christian Associations, business houses, railway associations, etc. Perhaps the most important work of the society in the past year has been done through its president, Professor Charles R. Henderson, who as a member of the American Society for the Scientific Study of Education, devoted the National Year Book for 1908 to the subject of education with reference to sex. The organization has given but few lectures. This work, however, has been taken up by the Chicago Women's Clubs and handled mostly by different women physicians. Possibly two hundred of such lectures have been given. In addition, a large number of lectures, especially to young men, have been given by Dr. W. S. Hall, of the Northwestern University Medical School. This society is also cooperating with the Illinois Vigilance Association, organized to fight the white slave traffic."

The Milwaukee Society was organized in 1906. Since its organization upwards of thirty lectures and talks before various organizations have been given to students, young men's bible classes, civic societies, schoolmaster's clubs, school-board committees, women's clubs, etc. "It is estimated that these lectures have reached five or six thousand different individuals. From every direction words of commendation have come. Openmindedness has been met almost without exception. We are looking forward to lectures in various parts of the city under the auspices of the City Board of Health. We have distributed a large amount of literature, especially that published by the Chicago Society."

The Indiana Society was organized in June, 1907. The first work of the association was to put forth a general educational pamphlet. "The work of publishing and distributing pamphlets was taken up by the State Board of Health. Thirty thousand have been distributed, and 25,000 more have just been printed. The lecture work of this society has been done chiefly by Professors Woods of the Medical Department of the Indiana University, who has given over fifty lectures in the past two years. Many lectures have been given by other members of the society; fifteen by Dr. Hurty, secretary of the State Board of Health, in different parts of the State. The influence of ministers and teachers has been sought, and a hearty response always secured. After a conference with the school commissioners and the superintendent of the public schools, circular letters were sent to parents of boys in the schools in regard to the advisability of instituting sex education in the schools. It is worthy of note that the replies received, about fifty per cent., were unanimous in favor of this instruction."

The St. Louis Society was organized January 25, 1909. "An address given by request before the St. Louis Medical Society was published in pamphlet form, 5000 copies of which were printed and copies sent to 1600 members of the Civic League, 400 members of the Women's Club, and to other influential organizations. The educational literature of the American Society has also been largely distributed, also several hundred copies of an address on the "Relations of Social Diseases and the Family." Arrangements are being made for lectures before church clubs, philanthropic and reform associations, pedagogical societies, department stores, labor unions, etc. The president of the Central Trades and Labor Council has written that his people are willing to cooperate in any way. We have met with nothing but encouragement, and cooperation has usually been assured as soon as asked. Our membership is steadily increasing, and we are now arranging a series of meetings in conjunction with various societies, clubs, and associations."

The Portland Society was organized December 10, 1907. The work has been principally directed to the circulation of literature bearing on sexual hygiene and personal and social purity among young people. A committee was appointed to prepare suitable literature. "Copies of the literature of the New York Society are on my desk and have been of great value in this work. It is the intent of this organization to do its work largely through pamphlets to mothers, fathers, and children. We believe that the home is the best place to give instruction in matters of sex."

The Spokane Society was organized October 23, 1908. The society has held six public meetings at various points in the city, at which addresses were given by Dr. Lyman Sperry and other distinguished speakers. "The year's work has been one essentially of duty and preparation. The executive committee, which meets twice a month, or oftener, has decided that its best and most far-reaching work must be the educating of young people in the community, and that the society should not go over the heads of the parents, but should take them into its confidence and urge upon them their duty in this respect. We have also sought to extend our educative work

among the young men of this community, anticipating a similar work among the young women. The committee has also given considerable time and study to the discussion of the subject of prostitution in our city, and while some light has been shed, this big perplexing question remains unsolved, etc. The society has published nine circulars, 43,000 of which have been distributed, and larger editions are now being printed. It is proposed to send certain of these circulars to all the men listed in the City Directory, and others to all the women listed."

The California Society, which has adopted the title of "The California State Association for the Study and Prevention of Syphilis and Gonorrhea," was organized April 19, 1909. It is worthy of note that the first pamphlet issued was published in the Official Bulletin of the State Board of Health. The president, Dr. Greene, has given many lectures throughout the state to professional and lay bodies. The work thus far has been devoted chiefly to the enlarging and perfecting of the organization.

No details have been received from the Denver, West Virginia, and Jacksonville Societies. The Mexican Society of Sanitary and Moral Prophylaxis was organized in 1908, under the auspices of the Academy of Medicine of Mexico. It publishes a bulletin of its transactions. There have been many interesting details omitted from these reports necessitated by the lack of time at my disposal for their enumeration.

Before proceeding to consideration of the ways and means by which the work of sanitary and moral prophylaxis can be most effectively carried on, I may be permitted to refer to the work done in other countries. It is to be understood that the movement in this country is but a part of a general movement which it is hoped will eventually be world-wide in its scope. Societies have been formed in France, Germany, Holland, and other European countries, and in the Argentine Republic of South America. Through the courtesy of Dr. Blaschko, the eminent secretary of the German Society for the Prevention of Venereal Diseases, organized in 1902, I am furnished with a report of its work during the past seven years. This society numbers nearly 5000 members, and has 20 local branches in different cities of Germany.

"The German Society for the Prevention of Venereal Diseases was founded on October 19, 1902, by medical and lay men, drawn from all circles of society. Its members now number nearly 5,000, including men of science, merchants, public officials, artists, and artisans, and even women, all classes of society being represented.

"So far as practical results are concerned the society may mention the following: The cancellation of discriminations against venereal persons formerly contained in the sick insurance law is due in the main to the intermediation of the German Society; in many towns the inadequate provision of beds for venereal patients has been arranged for through the direct and indirect instigation of the society by the creation of special departments under the superintendence of medical specialists; the departments themselves, formerly the stepchild of hospital administrations, are now equipped with all the auxiliaries of modern technique for the treatment of disease; the harshness and restrictions, oftentimes of a degrading kind, to which formerly venereal patients were exposed in hospitals, have now been everywhere removed. The opposition of the populace to their treatment in these departments has disappeared. At the universities chairs have been established for the teaching of venereology, while the latter itself has been raised to a subject of examination in the Medical State Examinations. At the instigation of our society a ministerial decree has been issued to have students of other faculties pass through a course of lectures on sexual hygiene in each semester; in most of the Federal States there are now courses on sex pedagogy for advanced high school students, following a resolution adopted at our Mannheim Congress. As these students are discharged from school, they are enlightened through medical lectures as to the nature and perils of venereal diseases; on certain evenings there are lectures for parents enabling the latter to deal competently with the sexual problem in the education of their children. In Prussia a ministerial decree has recently placed the sanitary police superveillance of prostitutes upon an entirely new basis which was likewise suggested by the work of our society.

"A monthly periodical is sent free to all members; there is a committee at work which, in conjunction with eminent specialists abroad, publishes a *Journal for the Prevention of Venereal Diseases* (*Zeitschrift für Bekämpfung der Geschlechtskrankheiten*, Joh. Ambr. Barth, Leipsic, publisher), which contains elaborate articles of a scientific character, and at the same time offers an opportunity for a thorough and detailed discussion of the questions at issue. Furthermore, the society has issued leaflets for both sexes intended to enlighten the public on the dangers of venereal diseases, and which are being distributed among the adolescent part of the populace. Five million copies of these leaflets have already been distributed, and the society has defrayed the expense of 4,000,000 of these. The society has also issued a series of popular pamphlets at moderate prices; traveling speakers go from town to town to address the public; and in order to educate it on the injuries and deformities which may be caused by venereal diseases, the society has made up a collection of plaster casts, pictures, and tables, which is being exhibited in the various towns and explained in lectures by physicians as to their importance and meaning.

"A special field of the society's work consists in making inquiries on various questions connected with the dissemination of sexual diseases, such as the conditions of living of prostitutes, inducing sexual excesses by the use of intoxicants, the prevalence of venereal disease in certain groups of the populace, sources of infection, etc. The material obtained by these inquiries is being published in the scientific organ of the society and will serve as an important basis for legal reforms.

"Taking everything into consideration, it may truly be said that the seven years' work of the German Society for the Suppression of Venereal Diseases has been very extensive, successful, and beneficient.

"Of no less importance than these direct practical results is *the absolutely unanimous approval of our aims on the part of the general public and the practically total change of front of periodicals* and the *daily press* in relation to the aspirations inaugurated by us; whereas formerly they were either completely ignored or obscurely hinted at, there is now, especially in the foremost publications of the land, an open, frank, and oftentimes highly intelligent exposition of the difficulties of the problems involved, the discussion of which the German Society has made its object and in the solution of which it is endeavoring to participate."

I have emphasized this paragraph, as it brings us face to face with the chief obstacle encountered in this work. The real difficulty is that we have been unable to reach the great mass of the public to any effective extent. The public press and periodicals which serve for the enlightenment of the masses, and which have rendered such signal service in the campaign against tuberculosis and other infectious diseases through the popularization of hygienic knowledge, are absolutely barred to the mention even of the diseases we wish to prevent. I believe that with publicity for a fulcrum we have in our facts a sufficiently strong lever to move the world of public opinion.

From personal conferences with the editors of a number of popular magazines in this city it may be stated that the question of presenting to their readers certain facts relating to the economic significance of social diseases, their danger to the public health, and their peril to the family and society is being seriously considered. Indeed, positive assurances have been given by the editor of perhaps the most influential and widely circulated of these magazines that this would be done so soon as a practical working scheme can be devised. Once the crust of conventional prejudice is broken by a courageous leader there is no doubt that other progressive periodicals will fall into line.

As regards other available openings for this educational work, we have found in the physical training department of the Young Men's Christian Association, with which a sort of affiliation has been established, a most cordial cooperation, both in our lecture work and the distribution of literature. At a recent meeting of the New York Association of Teachers of Biology it was resolved by this body to unite with the American Society of Sanitary and Moral prophylaxis, in a request to the Board of Superintendents to provide a course on sex instruction for all first-year pupils in the city high schools and to study and apply methods for teaching sex education along biological lines. Where there has been no official affiliation with the Women's Christian Temperance Union, the superintendent of its purity department has been most indefatigable in her efforts to advance the cause of sex education through the purchase and distribution of the educational literature of this society. A cordial, though less active, cooperation has been given by the National Purity Alliances and Federations. Among numerous bodies which have proved valuable allies may be mentioned the American Federation of Women Nurses, State Conferences of Charities, Federations of Women's Clubs, etc. The recently organized Public Health Education Committee of the American Medical Association will also, it is believed, render effective aid in this work. I might refer to many other organizations, such as labor unions, and labor associations, etc., which may be utilized in the expansion of this educative work.

In dealing with other phases of this prophylatic work it has been the policy of the society to secure when possible the cooperation of existing organizations which are working in the interests of the social welfare. As an illustration: at a recent meeting when the general subject for discussion was "The Affluents of Prostitution," papers were read on "The White Slave Traffic" by the president of the National Vigilance Committee; on "The Evil Influences of Dance Halls, etc.," by the chairman of the Committee on the Amusements and Vacation Resources of Working Girls; on "Demoralizing Theatrical Plays," by the president of the Society for the Prevention of Crime; on "Raines' Law Hotels," by the secretary of the Committee of Fourteen, with a discussion by representatives of various other organizations in this city.

While the regulation of prostitution, including the sanitary surveillance of prostitutes, is excluded from this society's scheme of prophylaxis, it is actively engaged in the more fundamental work of studying and endeavoring to correct the underlying conditions and causes of which prostitution is the product. Especially is it combating the twin forces of ignorance and social impurity which are the basic cause of that vast mass of disease and misery we are endeavoring to prevent. Its aim is not to make prostitution safe, but to prevent the making of prostitutes.

In a recent work on the Social Evil written from the standpoint of the reglementarists, the advantages and necessity even of the sanitary surveillance of prostitutes are strongly urged, while the protests of the abolitionists against certain odious features of this system, such as the arbitrary arrests and forcible examination of women of suspected virtue found on the streets, are dismissed as absurd. The dominant sentiment of the book is expressed in the concluding paragraph: "Less indulgence for the professionals of debauch; more protection for *les honnetes gens.*" The force of this appeal is weakened when it is reflected that the "honest men" can easily protect themselves by not voluntarily exposing themselves in sexual debauch. The sentiment of this society may be voiced: "More protection for young women who are too often made professionals through seduction, fraud, or force; less indulgence for the men who in robbing them of their virtue infect them with disease."

Brief reference may be made to another phase of this society's work, namely, prophylaxis by treatment. The work of the committee on treatment has been limited to the study of the existing conditions, and the exposure of defects in the present organization of our hospital system, which makes the most inadequate provision for the treatment of venereal patients, especially when the disease is in the acute contagious stage, and curative treatment is most needed. These and other glaring defects were brought to the attention of the Mayor's Commission on Public Hospitals last year, and as a result of these representations we are now assured that plans have been prepared for the construction of a large special hospital with ample provision for the accommodation of this class of cases.

There are one or two measures bearing upon the further development of this work to which I will allude in closing. One is the formation of a national organization; the other, the establishment of a bulletin or journal which shall serve as the official organ of all the societies. Tentative efforts were made two years ago to carry out these suggestions, but the conditions did not then seem favorable. A national organization, which would effect the solidarity of the different societies, working under a common name and with a common object in view, could not fail to give to this movement increased strength and a more commanding influence. In addition, it would insure concerted action and more effective work along definitely determined lines. In this federation of societies each would preserve its autonomy and independence as a local organization. The establishment of a bulletin or

journal which would serve as a medium of communication between the different societies for the publication of papers and proceedings of general and local interest, as well as for the propagandism of our ideas among the medical profession and the public, would give a powerful impetus to this movement. In the circular letters above referred to, an expression of opinion was asked from each society as to the advisability and feasibility of these proposed measures. There was a general approval of both propositions.

Another matter which appears to me of importance is a census of the venereal morbidity and mortality in this country, especially in the larger cities. As is well known, there is no official registration of venereal diseases, and the morbidity from this cause is an unknown and unknowable quantity. It is believed that the morbidity from this class of infections exceeds that of all other acute infectious diseases combined. If we had accurate statistics of the extent to which these diseases prevail in our civil population, as we have in our army and navy service, such data, showing their danger to the public health, their significance as a peril to the family and the race, to say nothing of their economic aspects, the enormous cost to the state and community in supporting the great army of defectives which fill our asylums and public institutions, would form the basis of an effective appeal to the public for support and cooperation in this preventive work.

56 West Fortieth Street.

FREUD'S CONCEPTION OF THE PSYCHONEUROSES.*

By A. A. BRILL, Ph.B., M.D.,

NEW YORK CITY.

CLINICAL ASSISTANT DEPARTMENT OF PSYCHIATRY AND NEUROLOGY COLUMBIA UNIVERSITY; ASSISTANT IN MENTAL AND NERVOUS DISEASES, BELLEVUE HOSPITAL; ASSISTANT VISITING PHYSICIAN, HOSPITAL FOR NERVOUS DISEASES.

The psychoneuroses, the step-children of medicine, have of late received more attention in the literature than before. Both here and abroad it has been realized that there is a large group of diseases, the so-called borderline cases in mental diseases, the understanding and treatment of which have been sadly neglected, and it is gratifying to know that at least some steps have been taken to meet these deficiencies. The wave of psychotherapy which has swept the continent has also made its presence felt in this country through the numerous discussions in both lay and professional journals. Abroad its adherents claim brilliant results; one need only review the numerous writings of the Nancy and other schools to be convinced that psychotherapy is no empty term, but an actual branch of medicine, and that in the psychoneuroses it is the only effective remedial agent.

Yet, whereas all schools agree that the psychoneuroses should be treated by psychotherapy, they all disagree as to the nature of the psychoneuroses. One need only scan through the recent works on hysteria to see what diverse views are expressed by the different investigators on the subject. These diversities, in my opinion, are due to the fact that most of the investigators in question have ignored one very important factor, namely, individual psychology. Without individual psychology the riddle of the neuroses, like the riddle of the psychoses, must remain unsolved.

Among the different views expressed on the neuroses those of Freud stand out most conspicuously. No recent theories either in medicine or psychology have evoked so many controversies and discussions. After years of careful and painstaking labor Freud evolved not only a system of psychotherapy but a new psychology. Unlike all other investigators, he discarded all generalities and confined himself to the individual. The individual factors which had escaped the notice of other investigators he found to be of the utmost importance in the psychogenetic development of personality.

As early as in 1895 Breuer and Freud published the "Studien über Hysterie." They found that hysterical symptoms like neuralgias, paralyses, epileptiform attacks, etc., could be traced to actual psychic traumata which the patient could not consciously recall, but which could be readily demonstrated when the patient was put in the hypnotic state. In other words, they found that the hysterical manifestations were not accidental but had a definite cause. The connection between cause and effect was often quite obvious; thus, "A very sick child falls asleep, and the mother exerts all her will power to make no noise to awaken it, but just because she resolved to do so, she emits a clicking sound with her tongue (hysterical counter-will), which was repeated on another occasion when she wished to be absolutely quiet. This developed into a regular tic which persisted for years."[1] In some cases the connection is not so simple, there being only a symbolic relation between the cause and the hysterical phenomena; thus, psychic pain may cause a neuralgia, and moral disgust may cause vomiting. Breuer and Freud then concluded that these psychic traumata, or the memory of the same, act like foreign bodies in consciousness, and even long after their occurrence continue to influence like new causative factors; in other words, "The hysteric suffers mostly from reminiscences."[2] This was proven by the fact that the individual hysterical symptoms disappeared without returning if one succeeded in thoroughly awakening the memories of the causal process with its accompanying affect, and if the patient circumstantially discussed the process giving free play to the effect. The reason for the strangulation of the emotion was because at the time of its occurrence it could not be adequately worked off. We all know that it is not always possible to give vent to our feelings, and that an insult retaliated leaves quite a different impression than one that has to be swallowed.

The treatment called "catharsis" consisted in reconducting the sum of excitement from its false paths to the original conscious idea, and then working it off by means of intellectual labor and speech. The patient was hypnotized and questioned about the origin of the symptoms, and while recalling the original injuries, either in hypnosis or the normal state, the hemmed-in emotions were discharged and the symptom disappeared. This is the so-called "abreagirung"—abreaction—which means to work off something by living through it again.

This is a rather brief review of the conceptions originally expressed by Breuer and Freud. It is from these principles that Freud developed his present conceptions of the psychoneuroses and his revolutionary psychology.

When Freud continued to practice the cathartic treatment he was confronted with one special dif-

*Read before the Section on Neurology and Psychiatry of the New York Academy of Medicine, October 11, 1909.

ficulty. He found that not all persons were hypnotizable, and as hypnosis was absolutely essential for the broadening of the patient's consciousness, many patients had to be given up as they could not be hypnotized. He even went so far as to take one of these patients to Nancy, to Bernheim, but after applying all his skill, Bernheim had to admit that he, too, could not hypnotize the patient. This, and a number of other reasons caused Freud to avoid hypnotism, and to adopt a new procedure which he calls the psychoanalytic method.[3] On asking the patients in the waking state whether they remembered the first motive for the symptom in question, some knew nothing, while others recalled something rather vaguely. Freud then applied the same method which Bernheim used in awakening the manifestly forgotten impressions produced during somnambulism. He found that by urging and assuring the patients that they did remember, and telling them that all they had to do was to concentrate their attention, and repeat the thoughts which would occur to them, they finally recalled the pathogenic ideas without hypnotism. But as this urging necessitated much exertion on his part, and showed him that he had to overcome great resistances in the patient, he formulated the following theory: "Through my psychic work I had to overcome a psychic force in the patient which opposed the pathogenic idea from becoming conscious."[4] The resistance was due to the fact that the ideas which had to be disinterred were all of a painful nature, adapted to provoke the affects of shame, reproach, mental pain, and the feeling of injury—they were altogether of that kind which one would not like to experience, and prefers to forget.

This gave rise to Freud's idea of repression (Verdrängung); the pathogenic idea being of a painful nature is incompatible with the ego, and is therefore treated by it as *non arrivé*. The patient wishes to know nothing about it, he wishes to forget it. But as this repression, or forgetting never succeeds completely, the pathogenic idea continues to strive to come to the surface, and is constantly inhibited by the psychic censor. This struggle of the two opposing forces results in a compromise. Each foregoes a part of the original demand, thus meeting the other half way, and the result of this mutual accommodation is then transformed into a hysterical symptom by the process of conversion. In this manner the ego frees itself from opposition, the original painful idea or unattainable wish is forgotten, and instead it becomes burdened with a memory symbol which remains in consciousness as an unadjusted motor or sensory innervation. We thus see that the main character of hysteria is not the splitting of consciousness, as asserted by Janet and his school, but the ability of converting the sum of strangulated excitement, either totally or partially, into that motor or sensory innervation which is more or less connected with the traumatic event. This is the psychological mechanism of hysteria.

There are, however, predisposed persons in whom there is no adaptation for conversion. Here, if an unbearable idea enters consciousness it meets with the same contrary forces as those mentioned above, the affect becomes detached from the idea, but instead of being converted into the physical it remains in the psychic sphere. The weakened unbearable idea remains apart from all association in consciousness, but its detached affect or the sum of excitement, allies itself to another indifferent idea,[5] which on account of this "false" connection becomes an obsession; or the unbearable idea is so changed that the patient does not recognize it. He no longer thinks of the painful or disagreeable, but instead he is troubled by an obsession, the absurdity of which he realizes, but from which he cannot rid himself. The advantage thus gained by the ego in the transposition or dislocation of the affect is not as great as in the hysterical conversion of psychic excitement into somatic innervation. The affect remains unchanged and undiminished, but the unbearable idea is suppressed from memory.

The same mechanism holds true for the origin of the phobias, and both come under the heading of compulsion neurosis (Zwangsneurose). It was also found that the unbearable ideas underlying the compulsion neurosis (obsessions and phobias) have their origin in the sexual life. In the words of Freud, "The obsession represents a compensation or substitute for the unbearable sexual idea, and takes its place in consciousness."[6]

Both hysteria and compulsion neurosis belong to the defense neuropsychoses; their symptoms originate through the psychic mechanism of defense, that is, through the attempt to repress a painful idea which was incompatible with the ego of the patient. In both neuroses the idea is robbed of its affect, and excluded from associative elaboration, but remains in consciousness.

There is still another far more forceful and more successful form of defense, wherein the ego misplaces the incompatible idea with its emotion, and acts as though the painful idea had never come to pass. When this occurs the person merges into a psychosis which may be called "hallucinatory confusion." To illustrate this form of defense I will cite a case which through the kindness of Dr. M. S. Gregory, I saw at the psychopathic pavilion of Bellevue Hospital. It concerns a young married man about 30, a New Yorker, who being out of work tried his fortune as a farm hand up the State. Things did not go as smoothly as he expected, and one day the farmer gave him a very severe thrashing, and chased him off the farm without paying him his salary. He sought redress, but could get none, so that he had to walk to New York City penniless. When he returned home he made a number of attempts to obtain justice for himself, but was told that he could do nothing. He kept on brooding over it for some time, when one day he suddenly became excited and confused. He became boisterous, cursing the farmer, and accompanied his utterances by violently kicking and punching the bedstead and the pillows. He imagined that he was punching the farmer. He was so excited and confused that his wife sent for the police, who took him to the psychopathic pavilion of Bellevue Hospital.

Here the idea was so painful that the ego tore itself away from it, but as the painful idea was inseparably connected with reality, the ego also excluded itself wholly from reality. Such cases give us an insight into the psychoses. Thanks to the genius of Freud and the Zurich School,[7] we no longer fear to face the hitherto considered perplexities of the insane mind. We know that every insane utterance, every morbid perception, has a definite meaning and a definite *raison d'être* when analyzed. Truly there is method in madness.

In tracing the psychic traumas which are supposed to be at the basis of hysterical symptoms or compulsion neuroses, one invariably comes to sexual experiences of childhood. This is so conspicuous that it led Freud to lay great stress on the sexual,

and to formulate the following sentence: "In a normal *vita sexualis* no neurosis is possible."[8] This, I know, will sound rather strange to some of you, but I would like to call your attention to the fact that the sexual impulse is one of our strongest impulses. It is the one impulse that is subjected to the greatest amount of repression, and for that reason it has always been the weakest point in our cultural development. You must also bear in mind that Freud's conception of the sexual is very broad. It is just as broad as our English word "love," or the Greek word "eros," and does not at all limit itself to the coarse sexual. Moreover, you must remember that sexuality is more complicated than one thinks. Hypocrisy and prudishness have from time immemorial taboed all things sexual; the word itself carries with it the ideas of lewdness and loathing. As a result of this, the ignorance displayed in matters sexual is appalling. Thus we are led to believe that there is no sexuality before a certain age, the age of puberty, yet when we look back to our own youth we find that long before that age we were subjected to certain feelings which were unmistakably of a sexual nature. Freud maintains that the sexual is born with us, and begins to manifest itself in infancy. I regret that the brief time at my disposal does not allow me to discuss the sexual theories expounded by Freud, but those of you who are interested in the subject should study his interesting and profound book, "The Three Contributions of the Sexual Theory."* I will merely add that after carefully studying the sexual development as no sexologist ever did, Freud came to the conclusion that hysteria is the result of a conflict between the libido and the sexual repression, and that the hysterical symptoms have the value of a compromise between both psychic streams.[9] We must bear in mind that it is the mental conflict which is the essential causative factor and not the sexual moment as such. The resultant compromise of such conflict generally causes the sexual wishes to be consciously rejected and unconsciously accepted. The wish is then repressed, but the sum of excitement finds its way into bodily innervation and forms the hysterical symptom.

Let me cite an example. A married lady of 49, who suffered from hysteria for over twenty-two years, showed as one of her symptoms a very painful contracted and paralyzed right arm which had been so for over three years. The muscles of the arm and shoulder region were completely anesthetic, deep needle pricks were not perceived, but the slightest attempt to straighten out the arm was most painful. Indeed, the pain was the chief symptom. It would be impossible for me to give you here the full analysis of this symptom; I will merely mention some of the psychic constellations.

Due to a number of sexual traumas sustained in childhood, all sexual feelings were repressed, and as a result she was totally frigid when she married. Indeed, coitus was both painful and disgusting to her. This produced marked marital unhappiness, her husband failed to understand her condition, and what made matters worse was the fact that he found her masturbating in her sleep. When he first noticed it he was very indignant and tried to call her to account for it, but she continued to sleep; he tried to arouse her, but she did not respond. He thought at first that she was shamming, but finally concluded that "she had a fit," and reported the matter to the family physician. This somnambulistic state during which she masturbated was repeated on an average of five to six times a week. There was complete amnesia for this action. She at first refused to believe it, but she was finally convinced of it by her own sister, who saw her do it on the occasion of sleeping with her. She then sought the aid of a physician who gave her large doses of bromide, and advised her to wear a sock over her hand and firmly tie her arm in complete flexion. While she was being treated for her masturbation it was reported to her that her husband carried on some illicit relations with one of the girls whom she employed. She absolutely refused to believe this, and no amount of urging on the part of her husband's own relatives could induce her to dismiss this girl. This girl was the daughter of a very poor woman, and it was out of compassion that she took her into her millinery establishment and taught her the profession. This state of affairs continued for months. She was extremely jealous, yet her pride would not allow her to take any action in the matter. It was after a quarrel about some other matters, during which her husband grasped her by the right arm, that it became painful, and developed into the condition noted above. As she was the moving spirit in the millinery establishment the business had to be given up, as she was totally incapacitated by her malady.

Here, as we see, the conflict was between the libido and the repression. The repressed sexual feelings made her consciously frigid but unconsciously passionate. When her masturbation was brought to her consciousness she took all the precautions to prevent it, but as usual she was unsuccessful. Her husband's faithlessness gave rise to another conflict. Her pride gained the upper hand, and she absolutely refused to believe what every one else saw and what she herself could not fail to see. When her husband grasped her by this arm, which was the cause of so much mental pain—it was the one with which she masturbated—the conversion took place. The symptom, as Freud puts it, was the result of a compromise between two opposing affects, one of which strove to bring to a realization a partial impulse or a component of the sexual constitution, while the other strove to suppress the same.[10] This symptom, as we see, served a double purpose, it stopped the masturbation and incapacitated her to such an extent that the business had to be given up, and the girl who caused her so many pangs had to go. The pain was also the punishment for the underlying sexual desire. She never masturbated with her left hand, nor has she ever been seen masturbating since she was cured by psychanalysis.

In analyzing neurotic symptoms Freud found that the dream played a great part in the individual's life. This gave origin to the epoch-making book, "Die Traumdeutung."[11] The dream is not at all absurd and senseless, but has a definite meaning when analyzed, and in the experienced hand it is the most valuable instrument for penetrating the mind. In the neurotic patient the subject of the dream generally refers to the origin of the neurosis, *i. e.* to the repressed material, but due to the many distortions and transformations only few and hidden associations show allusions to the repressed experience. Psychanalyis explains the different components of the dream, and thus reveals the repressed ideas which are at the basis of the neurosis. The dream is divided into the manifest and latent thoughts. The former are remembered by the dreamer on awakening, while the latter represent the thoughts

*An English translation in preparation.

of the dream before they were subjected to the distortion. When the translation is complete we find that the latent thoughts of the dream invariably contain the fulfilment of a repressed wish. The same holds true in the psychoneurotic symptoms. In the words of Freud, "The hysterical symptom, like all other psychic formations, is the expression of a wish fulfilment."[12]

In the same way the repression continues to evince itself in normal conscious life; in other words, the wish fulfilment normally manifests itself during the waking state just as it does in the dream and in the neurotic symptom. This can be readily seen if we analyze the abnormal or the so-called accidental actions of every day life. In his very interesting and instructive book, "The Psychopathology of Every Day Life,"[13] Freud shows that mere lapses of memory, speech, and writing, as well as the common mistakes are not at all accidental, but when analyzed have a reason. Thus the forgetting of a name which we have once known implies that either directly or indirectly there is something painful or disagreeable connected with it. A mistake in talking is usually what the speaker really means. In other words, the repression influences our waking state just as it does the dream and the psychoneurotic symptoms. Just as the latent thought of the dream, the psychoneurotic symptom represents a fulfilled wish, and both the dream and the neurosis seem incomprehensible until explained by psychanalysis.

I will now cite a brief analysis of an obsession. One of my patients, a young man 26 years old, suffered from a typical compulsion neurosis, the main symptom being an obsessive action which consisted in a rapid upward movement of his arms, as though holding back or pushing up something. This action became very annoying to him and his family. He was often compelled to do it in public, and it interfered with his work as a diamond cutter. Before proceeding with the analysis I will mention something concerning the technique.

On analyzing psychoneurotic symptoms the patient is required to lie on his back on a lounge, and the physician sits beind the patient's head at the head of the lounge. The object of this position is to avoid all muscular exertion and distraction, thus allowing a thorough concentration of attention on the patient's own psychic activities. We then ask the patient to tell all he knows of the symptom, and we usually find a number of memory gaps. These he is urged to fill in by concentration of attention on the subject and by repeating all thoughts originating in this connection. Before proceeding we must have the patient's promise that he will frankly repeat to us all the thoughts occurring to him in the order of their sequence, even thoughts that are painful or embarrassing. This is Freud's method of free association. We are also alive to the fact that the psychoneurotic symptom is merely a symbolic expression of the original repressed thoughts, and we therefore resort to Freud's method of interpretation, that is, we look out for symbolic expressions, psychopathological actions, and make use of the analysis of dreams. For unless one has mastered the triad of Freud's psychology, "The Three Contributions to the Sexual Theory," the "Psychopathology of Everyday Life," and the "Divination of the Dream," he is unable to use or judge Freud's psychanalytic method. With this digression we will now return to our patient.

On being questioned concerning his obsessive action it was found that it concealed the obsessive thought, "God may get into me." This thought obsessed him for months, and realizing the absurdity of it, he was ashamed to tell it to anybody. This was then followed by the obsessive action described above which was a protective mechanism against the thought, and signified, "I will pull Him out again." As the word "God" seemed to be the most important word in the obsession, I asked him to concentrate his mind on this word and tell me all the associations it recalled to him. He gave the following: God—father—I am always bothered by the foolish thought that God will get into me. He suddenly stopped, and on being urged to continue he said that something just occurred to him which had nothing to do with the thought of God, and which he would not like to tell unless it was absolutely necessary. On being told to continue, he stated that it recalled to him that about six months ago while being at work, a fellow working man once asked him to look out of the window, and when he did so he saw two dogs in the act of copulation. This was very embarrassing to him, he turned his eyes away from the scene, but he could not banish a number of fancies which then came to his mind. One thought was, "How would it be to get into the dog?" He soon repressed these thoughts, and kept on repeating to himself, "I will not get into the dog, the dog may get into me." Now, if you read the word dog backward you will find that it spells the word God, and gives the key to the whole obsession. For years this patient was in the habit of turning words about. He showed me a diary which was filled with mirror writing, which he used because he did not wish any one in the house to know his affairs. We note that he at first consciously changed the painful idea "to get into the dog" into "the dog may get into me," and as the idea was disagreeable it was repressed, and the word dog was then unconsciously changed into God. This completed the obsession.

The same mechanisms are found in the dream, in the neologisms of the insane, and in the normal. I am sure that the majority of you are aware of the fact that the Sesrun Club is the nurses' club, and perhaps few of you know that the Yvel Jewelry Company is the Levy Jewelry Company. The basis for each cryptogram is a painful idea. Nurses' Club neither looks nor sounds as dignified as Sesrun Club, which may pass as a millionaire's club, and the Yvel Jewelry Company looks better and is perhaps more profitable than would be the Levy Jewelry Company.

This is a very simple example of the psychanalysis of an obsession, perhaps too simple to impress some of you with the gravity of the work, but we cannot change the workings of the mind. Those who analyze psychoneurotic symptoms and the utterances of the insane[14] can always find such mechanisms. Do not, however, think that the analyses of this obsession and the afore-described hysterical paralysis were as simple as I presented them. I merely gave you the result obtained after weeks of painstaking work. It would have been impossible to read here the full analysis of any of the symptoms. It would have required many hours. Indeed, psychanalysis takes time; the treatment of a chronic case usually takes from six months to a few years, but the most refractory chronic cases have been cured by this treatment. Both cases mentioned were cured by psychanalysis after everything else was tried in vain.

I will now conclude with the remarks that Freud used in concluding his lecture on psychotherapy before the Vienna Medizinische Doktorenkollegium:

"Let us hope that with an interest for psychotherapy, purified of all hostile prejudice, you will help us to do some good in the treatment of severe cases of psychoneuroses."

STENOSIS OF THE LARYNX CURED BY INTUBATION.*

By EMIL MAYER, M.D.,

NEW YORK,

ADJUNCT ATTENDING LARYNGOLOGIST AND CHIEF OF CLINIC, EAR AND THROAT (OUT-PATIENT) DEPARTMENT, MOUNT SINAI HOSPITAL N. Y., CORRESPONDING FELLOW BERLIN LARYNGOLOGICAL ASSOCIATION, FELLOW NEW YORK ACADEMY OF MEDICINE, FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, ETC.

These cases of laryngeal stenosis, three in number, were all due to different causes: the first was due to a gunshot wound, comminuting the thyroid cartilage, the second a post thyroid perichondritis, and the third a recurrent granuloma of the larynx. The cases are of special interest, firstly, because of their very unusual nature, and, secondly, because of the exceedingly satisfactory results following intubation. As no similar cases have been previously treated in this manner, the writer deems them of sufficient interest to place them on record.

Case I.—The first case is previously recorded (*Journal of the American Medical Association*, October 27, 1900), and, in brief, is that of a soldier who was shot in the battle of El Caney on July 2, 1898, the bullet striking the right frontal bone directly over the right edge of the orbit. The bullet had a most remarkable course (the man was lying down when struck), entering the right frontal bone, crushing through the superior maxilla, cutting through the soft palate, comminuting the thyroid cartilage, entering the esophagus where, being spent, it dropped into the stomach; some weeks later it passed per rectum. One month after the injury his dyspnea became so intense that a tracheotomy was performed on December 5, 1898. Four months thereafter he was placed in my care.

Until this time various diagnoses had been made, but none of them connected his gunshot wound with his laryngeal stenosis. The large hole in his soft palate made me suspicious of the nature of his illness and a careful investigation into the whole history cleared the matter up. The interior of the laryngeal infundibulum did not even admit the small probe. The inner walls of the larynx bulged at the center and the lowest portion was on a line with the false vocal cords; there were absolutely no voice sounds whatever.

At first the Schrötter tubes were introduced of increasing sizes and later on he was intubated, coughing up the tube after a few hours. The introduction of the intubation tubes through the firm mass was always a slow process during which the patient's air was so cut off as to give him great distress and make him cyanotic. To relieve this I devised a hollow handle made for me by Geo. Ermold, New York, to be attached to the intubation tubes. This worked very satisfactorily, I could now take all the time I desired to intubate, the patient breathing through the tube and handle while the tube was slowly introduced.

Owing to the malformations in his larynx the tubes would be coughed out within a very short time, the longest period that these tubes remained was four days. I then had recourse to the device of John Rogers, Jr., of New York City, which consists of an O'Dwyer tube with a screw piece attachment, the latter being introduced through the tracheotomy wound; this tube remained *in situ* for six weeks, during all of which time he was unable to swallow food, requiring esophageal tubes. With the removal of the tube his respirations were free, the voice clear, and the tracheotomy opening closed.

Ten days later, following an attempt to remove some tissue within his larynx, dyspnea set in which became so great that I was compelled to reopen the tracheotomy wound in my office and insert the tracheotomy tube. The patient would not allow further intubation, none of my persuasions being of any avail, though I am confident that he would have done perfectly well and remained so had he permitted it.

It is quite likely that the pension laws of our country were responsible for this determination as the presence of a tracheotomy tube constitutes permanent disability with large payments monthly, while a cured individual would only receive a small amount.

Case II.—The second case was that of a post-typhoid perichondritis of the larynx (Medical Record, July 25, 1903, and Transactions of the American Laryngological Association, 1904, page 147), and occurred in a female aged 28 years, first seen by me on January 19, 1903, with a history of having had typhoid fever three months previously. For the increasing dyspnea tracheotomy was immediately required. Gradual dilatation with Schrötter's tubes for about a month, followed by intubation under chloroform, the tube being worn for six weeks. Reintubation eight days later for increasing dyspnea. The tube being retained for three months continuously, during all this time she swallowed food well, and had taken a sea voyage absenting herself for two months from the city. She was

*Read before the Sixteenth International Medical Congress, at Budapest, September, 1909.

then extubated, but twelve hours later dyspnea ensued requiring reintubation later with a small metal tube; three weeks later the tube was removed and never again introduced. She was first intubated in April and wore an intubation tube most of the time for five months.

It is now five years since the tube was last removed, and while some thickening exists over the left inner surface of the thyroid, she has no discomfort whatever in breathing, though her voice is pitched much lower than formerly, and there is some hoarseness. The case then is recorded as being entirely cured by intubation, and the author believes it to be the first case of this affection so recorded.

Case III.—The third case is here presented for the first time. John M., native of Hungary, age 28, was admitted to the first surgical division of Mount Sinai Hospital with the diagrams of papilloma of the larynx. The previous history was good. While working in the tunnel under the East River he began to cough and had deafness in the left ear, cough ceased but hoarseness remained, which increased gradually and for six months patient has been unable to speak above a whisper, no dyspnea; the laryngeal examination showed a papillary growth involving both vocal cords with fairly marked stenosis.

He was operated upon December 3, 1907, under gas and ether anesthesia. The cricoid and thyroid cartilages were slit open and the interior of the larynx was exposed, showing the vocal cords symmetrically covered with a papillary growth. The mucous membrane was widely excised to be sure of being clear of the growth, then the mucous and muscular linings of the larynx were separated with an elevator-knife and scissors and finally removed, thus leaving most of the thyroid cartilage bare and a bare oozing space at the upper margin of the larynx just below the arytenoid folds. All raw surfaces were freely cauterized with crystals of trichloracetic acid (cocaine 10 per cent. and adrenalin sol. 1-1000 being used freely during the operation), the upper rings of the trachea were divided, and a tracheotomy tube was inserted into the lower angle of the wound; the thyroid was sutured. Pathological examination of removed growth reports it to be a papilloma.

There was some post-operative hemorrhage from the laryngeal branch of the superior thyroid which was promptly checked. The laryngoscopic examination was made by myself when I first saw him on December 20, 1907, seventeen days after the operation. Both arytenoids were found infiltrated, the right especially, much mucus was in the larynx, and there was a granulation area at the site of the right vocal cord and false cord. On the third of January there were granulations diminishing the lumen of the larynx to one-third of its normal size and Schrötter's tubes were introduced every second day. The tracheotomy tube had been removed a week previous, but dyspnea becoming severe, incision through the cicatrix and reintroduction of the tracheotomy tube became necessary.

On January 24 a large-sized, hard-rubber intubation tube was introduced and the tracheotomy tube removed; this was coughed out the next day and replaced. The next day he coughed out the tube again and having some dyspnea the tracheotomy tube was reinserted. He was then intubated from time to time, coughing up the tube and having the tracheotomy tube reinserted, the tube never remaining more than a few hours. On March 16, 1908, a metal intubation tube with the Rogers attachment was introduced. The tube was kept in position for four weeks and on April 13 it was removed, the patient being able to take food fairly well during the whole time of wearing the tube.

Some small pieces of granulation tissue were removed endolaryngeally, and on April 29 the examination showed except for some slight protuberance at the site of the right vocal cord no thickening within the larynx. The patient was discharged from the hospital wards as cured with a hoarse, but fairly loud, voice.

One and a half years have now elapsed since his discharge from the hospital wards, but as he has been an employee of the hospital since then there has been abundant opportunity for observing him and there has been no return of any dyspnea. Some granulations have appeared from time to time which have been removed endolaryngeally, so that he is entirely cured after the constant pressure of a metal intubation tube for four weeks only, to control the wild exuberance of granulation tissue.

A résumé of these three cases, showing remarkably unusual causes of laryngeal stenosis, is a striking illustration of the very great advantages of intubation and of the toleration of the intubation tube when patiently and persistently introduced.

The use of the hollow intubator in cases in which slow intubation is necessary, and the great advantage of the Rogers modification in appropriate cases is also established. Without the O'Dwyer tube these patients must all have been condemned to wear a tracheotomy tube or depend upon a tracheal opening for the remainder of their lives.

A STUDY OF THE EUSTACHIAN TUBE IN RELATION TO THE RADICAL MASTOID OPERATION.

By SEYMOUR OPPENHEIMER, M.D.,

NEW YORK.

ADJUNCT OTOLOGIST MT. SINAI HOSPITAL; OTOLOGIST AND LARYNGOLOGIST GOUVERNEUR HOSPITAL; OTOLOGIST AND LARYNGOLOGIST PHILANTROPIN HOSPITAL.

In chronic suppuration of the tympanic cavity, one constantly finds that without apparent lesions of any significance in the mastoid process and with more or less limited pathological changes in the middle ear itself, nonsurgical treatment, even for long periods of time, is of but little benefit, and, while the suppuration may almost disappear, yet the secretion again returns and the conditions are the same as if treatment had not been carried out. In such cases as these, careful study of the individual will show that the aural discharge is largely mixed with mucus and that each increase in the discharge is generally associated with an active catarrhal process in the nasopharynx, so that it at once becomes evident that the eustachian tube is the source through which the recurring and often continuous reinfection of the tympanic cavity is maintained. Not only in these cases, but in practically all instances of chronic suppurative otitis media, the tube in this capacity plays a more or less prominent rôle in adding to the changes occurring in the tympanic cavity, and for these reasons it becomes self-evident that in performing the radical operation for the cure of a chronic purulent otitis, it is essential that especial care be given to the tube in order to eliminate it as a factor in reinfecting the eviscerated cavity and

rendering the operation a failure by having a continuance of the suppuration from this source.

The object of the radical operation is to remove all diseased tissue and to render the auditory apparatus in this relation as free from infection as possible in order to have a successful result, and to obtain this the anterior wall of the tympanic cavity must receive its due share of attention while performing the operation, and to remove all sources of infection that may remain or subsequently develop in this locality. Just as much as the various parts of the mastoid process, therefore, should the Eustachian tube be considered an integral portion of the auditory tract from the operative standpoint in such cases where evisceration is demanded, and it is not only wise but essential that all portions of this tract be made surgically clean, and as such is not possible at the pharyngeal terminus of the tube, measures must be directed to obliterate the tympanic end in order to prevent continuous reinfection of the aural cavity made by the operation and thus prevent the neutralization of the favorable results to be expected as a result of the operative procedures.

The relation of the tube to the radical operation not only depends on what has been stated, but in carrying out measures for its occlusion much is gained towards prompt healing of the parts, and, at the same time, further steps are taken towards the process of epidermization of the osseous cavity, so necessary to the complete cure of the suppuration. As regards structural continuity, the nasopharynx is closely associated with the tympanic cavity by means of the eustachian tube, as the mucous membrane is continuous, and, therefore, as far as this structure is concerned, it is subject in all its parts to the same pathologic changes, so that morbid conditions of the nasopharynx, especially when associated with alterations of secretion, markedly influence any preexisting aural affection, and especially so in chronic aural suppuration of such persistance or severity, as to necessitate the performance of the radical operation. In this way, therefore, the Eustachian tube must be seriously considered as partaking of these morbid changes and transmitting them by direct continuity to the middle ear cavity. The mucous membrane also plays a prominent rôle in this respect, as in some parts it acts as a periosteum which in itself decidedly magnifies the importance of pathogenic lesions, especially of the osseous portion of the tube and at its tympanic opening.

It is essential in this respect to consider the anatomical relations of the tube to the auditory tract as bearing on the subject of its pathological changes in the light of operative procedures, as a knowledge of these relations will make clear the various reasons why special care of the tubal opening into the tympanum is so essential to obtain aseptic results and prevent the dangers of secondary infection after operation. Extending from the anterior wall of the tympanum downwards and forwards, the tube varies in length from thirty-three to forty millimeters, and of this, the part which concerns us here in relation to osseous lesions is that of the bony portion, which is from ten to fifteen millemters in length. The shape of this portion of the tube is important in a surgical sense, as a knowledge of it, as will be seen later, aids in selecting the instruments best applicable to remove diseased tissue at its tympanic mouth. Roughly, it presents a three-sided lumen, with its semiangles not abrupt but rounded off, while in general, it presents the shape of a blunt cone, the summit being directed towards the apex of the petrous portion of the temporal bone and its base opening on the anterior wall of the cavum tympani, so that considered as a whole, it will be seen that its largest diameter is at the tympanic end corresponding to the base and the apex is at the point where the osseous and cartilaginous portions join constituting the so-called isthmus.

The tympanic orifice measures from three to five millimeters in its vertical diameter, where it has fully broadened out from its narrow isthmus and it merges not by sharply defined limitations into the tympanum, but rather imperceptibly at the level of the upper third of this cavity. While the figures of the size of the opening are the usual average, it varies considerably, so that the opening here is inconstant and irregularly defined, although this is not of much import in considering its surgical relations from this aspect. The boundary between the tube and the tympanum is rendered still more irregular by the position of the walls of the latter in relation to the opening of the tube, as at the point of emergence the superior and lateral walls of the drum cavity merge into the former and without apparent osseous interruption in many specimens, form an irregular area here most difficult to describe.

Practically (and especially must this be borne in mind in operating here) the osseous portion of the tube lies entirely in the petrous portion of the bone, while as regards the relation of the tube in a surgical sense, its anterior wall is made up of a portion of the pars tympanica. The inner wall is composed of a delicate osseous layer not infrequently dehiscent in part, separating it from the carotid canal, while the upper wall is formed internally by the septum of the tube and the floor of the canal containing the tensor tympani muscle and outwardly its wall unites with the osseous tissue in the petrotympanic fissure. Of all these relations, that in direct connection with the carotid artery is the most important, as there is but a delicate lamella of bone between the osseous wall of the tube and the internal carotid artery, and for a short distance the wall of the tube forms the wall of the artery, so that it is essential in curetting here, either to obliterate the mouth of the tube by removing the mucous lining, or to remove minute areas of necrosed bone, that great care be exercised in gently handling the curette, as under such circumstances one is working directly on the artery and serious if not fatal hemorrhage may ensue if these relations are not properly appreciated.

When the mucosa of the tube is thickened, the glands are functionally more active, both relatively and absolutely, and a catarrhal condition of the nasopharynx exists at the same time, as is so often the case in chronic aural suppuration. It will be found then that the tube in this relation to the tympanum plays a not inconsiderable part in maintaining the purulent discharge, by constantly reinfecting the ear with the mucus derived both from its lining and carried through it from other portions of the respiratory tract. Not only, therefore, is treatment of these parts necessary in endeavoring to cure the suppuration by the usual routine measures, but it is also essential when operation is indicated, and while we cannot always remove by operation the catarrhal changes in the tube, yet such sources of infection can be eliminated by obliteration of its tympanic orifice, so that following the first coryza, which the

patient has after the radical operation, the parts will remain in good condition and not give evidence of a return of the suppuration from this source.

The bony canal of the tube may act as the route by which pus is conveyed from the tympanum to the retropharyngeal tissues, with the development of a pus collection at this point possibly obscuring the ear as the original cause of the trouble and especially may this be the case when carious areas develop around the tympanic orifice of the tube on the anterior wall of the tympanum. Such a case is recorded by Knapp, of otitic retrophyaryngeal abscess formed by the pus flowing from the tympanum posteriorly to the pharynx, along the semicanal for the tensor tympani muscle and the tissues about the Eustachian tube.

From these facts, therefore, the condition of the tube should be ascertained as far as possible, previous to operation, and especially so if the chronic discharge from the tympanic cavity has been found to contain mucus in any amount, thus suggesting this tubal factor as being prominent in the continuance of the aural discharge. Should it be found, previous to operation, that the tube seemingly plays no part in the continuance of the suppuration, and that there is a permanent occlusion from stenosis of its caliber in the osseous portion, it will hardly be necessary to consider its obliteration later, as this has already been accomplished by the pathological process. It is best, however, not to depend entirely on this preliminary investigation, but to examine carefully its tympanic orifice during the operation, especially for the presence of caries, and then, from the results obtained by this final examination, determine as to the proper procedures to be pursued.

Rarely, however, will the anterior wall of the tympanum in the region of the eustachian tube, or the osseous walls of the tube itself, be found to be the seat of a carious, or necrotic process, although the mucous membrane and periosteum covering these parts are quite frequently involved by morbid changes. This undoubtedly results from the fact that the brunt of the pathological process producing the continued suppuration is located posterior to this area in the region of the attic, antrum, and mastoid structures, and, further, that from the location of the tubal opening to the tympanum and its accessory cavities, drainage is not interfered with, as a rule, in this particular site. But of still further import in ascertaining the infrequency of caries here, is the structure of the osseous tissue composing this wall of the tympanum and the walls of the tube, as it will be found that the bone is hard and dense in structure, although, of course, the comparative and even actual thinness of some portions renders it rather fragile. As this follows the well known rule that cellular or spongy bone is more liable to carious processes than dense or compact bone, it accounts for the comparative infrequency of caries at this point and the frequency with which such changes are found in the mastoid process, and especially in those portions of it which partake of a pneumatic structure.

When for various reasons the tube remains patulous following operation, whether efforts have been made to close it or not, should a purulent or mucous discharge occur in the cavity of the tympanum, it may be diminished or completely stopped by washing out the parts with a eustachian catheter from the pharyngeal orifice, but as far as possible such a condition as this is not to be desired, for while the operation has removed the danger of serious sequelæ, yet it is also performed in order to cause a complete cessation of the discharge, and unless this is accomplished, one does not feel that a complete success has been obtained. While it is perfectly possible to obtain a perfect cure with a patulous Eustachian tube, yet such is of necessity not to be advised for fear of future infection, and in cases associated with cholesteatomata formation the tube should also be rendered impermeable, although Redmer thinks that surgical closure is not necessary for the permanent cure of cholesteatoma, as he has had a cure for ten years with a patulous tube.

During the course of the radical operation, when is it advisable to obliterate the tube? This may be done at any time after the mastoid has been eviscerated and the posterior wall of the external canal removed so that free access can be obtained to this region. When the bone has been removed in great part and the anterior tympanic wall is freely exposed to view the mouth of the eustachian tube should be curetted thoroughly but carefully with the sharp curette until all granulations are removed, so that healthy granulation tissue will form and aid in epidermization and occlusion of the tube at this site. In this way, if the usual asepsis be maintained, healthy granulations develop at this point and a firm cicatrix forms, so that as healing progresses the tube becomes firmly occluded.

Again, the tube may be ignored at the time of the primary operation except to remove carefully any necrosed or carious bone present in this locality. During the course of the after treatment of the osseous cavity in the temporal bone, the mouth of the tube may from time to time be cauterized to prevent the subsequent passage of septic matter, and, by these repeated cauterizations, to endeavor to form a cicatricial occlusion. Such treatment, however, is not to be recommended, as it exposes the ear to infection, and, furthermore, it is unnecessary as this step of the procedure should always be completed as part of the primary operation.

When curetting the tube during operation, it should be obliterated as thoroughly as possible by removing the diseased bone and all the mucosa for a distance from its opening. For this purpose, small oval, or round curettes are necessary, so that they can pass well into the mouth of the tube. All depressions or rough areas of bone in the neighborhood of the tubal orifice should be carefully removed with the curette, but great care must be exercised in doing this in the vicinity of the carotid canal, as dehiscences may be present and the artery may be injured with serious results. If skin grafting of the mastoid cavity is to be performed at the time of the radical operation special care must be taken in placing the epidermis in the mouth of the tube, and in order to utilize this as an additional obliterating aid, it should be forced well into the tube, so that the parts of their mucous membrane denuded by the curetting, will be thoroughly covered.

While failure of this part of the operation may result from not removing the carious bone in this vicinity, yet a patulous tube from this cause is rather infrequent, as the carious process rarely extends any distance into the lumen of the tube and the diseased osseous tissue can, as a rule, be readily removed as in other parts of the operative field. Even after careful curettment, however, occlusion may not always be obtained, and then frequent relapses with the persistence of suppuration are observed and examination shows the growth of ex-

uberant granulation tissue around the tympanic mouth of the tube. Should such be the case, a secondary operation may be performed and the parts again curetted and treated as before, or favorable results may be obtained after treatment extending over a more or less lengthy period of time by cauterizing this part with the galvanocautery. In some cases, one or two applications of the cautery lightly applied to the granulation tissue here are sufficient to produce a permanent occlusion by a firm cicatrix, if dead bone be not present.

When dressing the cavity in the bone immediately after operation the mouth of the Eustachian tube should be firmly tamponed, and during the course of the after treatment, the same method of tamponage should be carried out, that is, to tampon this part firmly at each dressing until obliteration has been assured.

45 East Sixtieth Street.

STUDIES WITH THE WASSERMANN REACTION.*

By E. CORSON WHITE, M.D.,

PHILADELPHIA,

AND

S. D. W. LUDLUM, M.D.,

PHILADELPHIA,

INSTRUCTOR IN NEUROLOGY AND NEUROPATHOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

The part played by syphilis in the production of diseased conditions of the nervous system has been under discussion for many years. If the complement-fixation tests prove unquestionable, these problems will be much simplified. Already the Wassermann reaction for the diagnosis of syphilis has given rise to an enormous amount of work which, despite individual variations and modifications of technique, have been uniformly confirmatory of its value as a means of clinical diagnosis.

In the following report an attempt has been made, while studying those nervous diseases due directly or indirectly to syphilis, to compare the Wassermann reaction, the Noguchi modification (using, however, the fluid reagents), and the globulin tests. The precipitation tests were included at first, but discarded, our results according entirely with other observers, the largest percentage of positive results occurring in parasyphilitics, and the next highest in nonsyphilitics.

The technique of the complement deviation tests, Noguchi and Wassermann, have been so often described that we will not repeat them. In every series of tests the quality and strength of all reagents, including a series of antigens, were carefully tested, and dosed by the same normal and syphilitic sera and same complement.

These antigens were alcoholic extract of syphilitic fetal liver, normal liver, guinea-pig heart, guinea-pig liver, lecithin, sodium, taurocholate, sodium glycocholate, and three different mixtures of bile salts and lipoids. These mixtures so far have not given satisfactory results, and are not included in this report. The glycocholate and taurocholate also were unsatisfactory and are omitted. Every test was fully controlled with normal serum, syphilitic serum, and, when possible, by serum of some nonsyphilitic disease.

There was a marked uniformity of result with all four tests. The Noguchi modification was in most cases more sensitive than the Wassermann, this increased delicacy making it give positive results in nonluetic conditions (tuberculous meningitis, one case). The most positive results with the fixation tests occurred in active secondaries, and the faintest in the treated tertiaries. The intensity of the complement fixation tests showed a direct relation to the acuteness of the manifestations and absence or incompleteness of treatment, or length of time since thorough treatment, but showed no relation to severity of the lesion. The Noguchi butyric acid and the Gay and Fitzgerald euglobulin test varied little in end results. The globulin tests were more often positive in parasyphilitic cases where the deviation tests were less constant. It is of great value, as corroborative evidence in distinguishing between brain tumor and cerebrospinal lues, where the fixation tests were often partial or absent.

The Noguchi butyric acid test, when applied to cerebrospinal fluid, gave a positive result in every luetic case with meningeal involvement, but failed in one case in which there was no involvement of the nervous system but a gumma of the liver, the blood serum of which was faintly positive. The test was positive also in every meningeal disease examined without reference to cause. The euglobulin was negative in nonluetic meningeal conditions, but present in some acute infections, tonsillitis, and pneumonia. Both of these tests fail if serum is bloody or tinged with hemoglobin.

In the Wassermann tests, in which three or four antigens were used, we found that luetic fetal liver, normal liver, guinea-pig heart, and lecithin ran roughly parallel, the titers for the different antigens varied even when the dose had been determined for all antigens with the same normal and syphilitic sera. In five of the primary cases, the reaction was studied with at least four, and whenever possible more antigens, and in these, during a period of twenty weeks, we observed the same general curve. Lecithin and guinea-pig heart being closest in titers to the fetal liver. In these cases the reaction was positive, first with the Noguchi modification, later with the Wassermann, using the luetic liver and lecithin antigens.

In the parasyphilitic disease the titers were less in early than in later stages. In tabes we more often had a positive reaction when there were active manifestations. One case reexamined during a seemingly latent period gave no change in the reaction, while another whose first test was very faintly positive to Noguchi modification, and negative to Wassermann, gave a definite positive to both tests in a second examination following the development of a hemiplegia. The stronger reaction where both serum and cerebrospinal fluid were used was found in the serum to both the Noguchi and the Wassermann techniques, but in cases where the serum alone was tested, the Noguchi technique seemed more delicate, while in cases where the cerebrospinal fluid was examined the best results were with the Wassermann technique.

Concerning the diseases studied little need be said. In the hemiplegic cases, amyotrophic lateral sclerosis, pseudobulbar palsy, epilepsy, and one brain tumor case, a definite history of syphilitic

*The material in this report was taken principally in the Neurological Wards of the Philadelphia Hospital, in the service of Dr. James Hendrie Lloyd, and the cases were collected under his diagnostic guidance. The work was done in the Laboratory of Neuropathology of the University of Pennsylvania with Dr. Spiller.

infection was obtained in all but one of the positive reactions. This patient, a hemiplegic, thirty-two years old, markedly improved under specific medication with which he had been treated for a month before the reaction.

A Wassermann reaction means syphilis active somewhere in the body, and the present trouble may be due to an entirely different cause. A positive pneumonia case seen at autopsy had a gumma of the liver. A positive reaction in this case could easily be recorded as a positive pneumonia. It is not improbable that many times a low grade syphilis may be present, thus making a soil suitable for another infection. Winfield, examining twenty-nine children with tuberculous joint disease, found physical signs of hereditary lues in ten cases, Pirquet reaction in twenty-eight of the cases, Noguchi modification in ten cases, a report strongly suggestive of the presence of both infections.

Seven suspicious pregnant women examined by us gave negative results. Five of these were again examined with the children after labor, with consistent results, except that one baby gave a partial response, but so far it has developed no signs of syphilis. Bar and Duanay think there may be some other factor present in the blood of the newborn which modifies the reaction. They found this weak reaction usually present in sera with bile pigment, or in a lactescent serum. With these two other doubtful mothers and their infants were examined, and were both positive.

Bar and Duanay[1] found the reaction frequently negative in infants whose mothers had been thoroughly treated, and at times in infants whose mothers had florid syphilis, but the highest positive results appeared in those cases in which the disease of the mother was latent. A positive test in the mother justifies treatment of mother and child, but the best prospect of success in treatment lies in energetic mercurialization before and during pregnancy. In the case of a child of a Wassermann-positive mother, which itself gives at birth a negative result, the reaction may later become positive, suggesting the possibility of infection during delivery.

Baisch[2] found in mothers of typical syphilitic children only about 75 per cent. which reacted with the Wassermann test, although he thinks all the mothers were infected. On the other hand, positively luetic mothers may give birth to infants which give negative reactions and remain free from signs of disease. In our cases, we examined the milk in six of these cases, and obtained a positive reaction in the two luetic cases. The reaction was faint in both, and so faint in one by the Wassermann that, except in the light of other findings, it would have been counted negative. In both these cases specific medication was carried out in child and mother, and, except for an eczematous rash on the genitalia of one child, all have been perfectly well during six months of observation.

In five cases of primary, nine of secondary, seven of tertiary, four of cerebrospinal lues, and four hereditary cases, we were able to make frequent examinations of the serum while under treatment for a period of six months.

In the primary cases the reaction was negative until the third week. One gave a sluggish negative to the Noguchi modification in the second week, but was distinctly positive at the third week to the Wassermann and Noguchi modification. These early cases and those latent cases giving negative results may be due to a state of equilibrium existing between spirochete and tissue of host. The variations in the number of positive results in primary cases of different observers are probably due to differences in the duration of the disease when blood was taken. The length of this negative period must depend on individual reaction to toxin, and to the malignancy of the infecting organism. Blumenthal and Roscher[3] found the reaction negative until the sixth to the eighth week. Levaditi, Laroche, and Yamanuchi[4] found it as early as the fifteenth day, and Lesser[5] reports one case where the reaction appeared before the initial lesion.

After the appearance of positive inhibition in our cases, the reaction gradually increased in intensity until modified by treatment. This modification is not always distinct, but follows a definite curve, which does not correspond with, or run parallel to the clinical signs, and varies markedly in different individuals. The Noguchi modification followed the same general curve. The change in intensity of reaction was in every case gradual, and in one case a sudden increase occurred in reaction with no increase in clinical manifestation, and in another (L. M.) there was increase in symptoms with no increase in reaction. In these cases the treatment was in every case inunctions of mercury, and when, despite treatment, the reaction continued to increase in intensity, injections twice weekly of calomel 0.1 gm. were added, with an immediate change in the reaction. In every case when the reaction first became negative, it was repeated, using (1) the nonheated serum, (2) serum to which 1/3200 of N (HCl) was added. In one instance each the reaction became positive again with this manipulation. This never occurred with a normal serum.

In some cases of disease the reaction becomes negative quickly, in others even intense treatment fails to secure a total negative reaction. In one case the lesions yielded very promptly, but at the last examination (4 months) the reaction was still rather strongly positive. In some cases the reaction will become negative without further treatment, as it did in one case of ours. In two of our cases, treatment was stopped by patients at healing of the lesion, and recurrance has already taken place in one, and the reaction is present in both. Blascho[6] thinks that treatment should continue until hemolysis occurs promptly but continued as long as it is sluggish.

Pürckhauer[7] found 35 per cent. of primary and secondary cases became negative under treatment, and thinks that a positive reaction should always be considered indication for further treatment, continuation of the reaction indicating a stubborn case, and a negative reaction should mean response to treatment; and when, after repeated tests at intervals, the reaction remains negative, the patient is cured, or is not at present suffering from a manifestation of the disease. In the primary cases all but one became entirely negative—this man was alcoholic. Two developed profuse general rashes. Of the secondaries six became negative, and the others faint. Of the tertiaries three are practically negative (sluggish), two faint, and two have moderate reactions. Of the cerebrospinal lues all are fainter than at the beginning, but are positive. The same is true of hereditary cases. All the negative tertiary cases we report had had long series of treatment. Two negative secondaries after suspension of treatment became positive again. In

three cases in which iodides alone had been given, there was in two no change in the reaction, and in one a slight increase. Blascho succeeded in changing the reaction with iodides. In one case of overmercurialization atoxyl was substituted. The patient had at that time a weak specific reaction, and, after three weeks, the reaction remained practically the same. There was a very slight increase in titers. Alcohol, Blascho[8] thinks, interferes with the change in reaction, and in one of our primary cases this was true. He found that the reaction faded gradually until it became negative, then gradually increased until it was positive again, and treatment was again instituted with a like result. The length of time the reaction persists after subsidence of active symptoms varies greatly. Fleischman found it in some six to nine months, in others, usually severe cases, three to four years. In one case of cerebrospinal lues, there had been no manifestation of disease for three years, and partial reaction was present. In another case it was negative seven months after trouble, at nine months was still gone, and at one year was again present. At this time the man had a severe attack of gastroenteritis. In this case it looked as if a new infection had aroused this entirely quiescent syphilis to activity. This return of reaction may occur without clinical signs, and did in this case. The man was, however, put on injections and inunctions immediately upon discovery, and reaction is again negative. Hoehme found that the least change in reaction occurred under treatment by mouth. Thirty-three per cent. changed with inunctions, and the most definite changes occurred with the intramuscular injections. In our experience the most pronounced change in reaction was in the use of two avenues of entrance, preferably inunctions and injections. In early cases the change was more marked than in the later phases of disease. In the later stages, to secure a negative reaction, the treatment must be more vigorous than at present used. In hereditary cases Lesser, Blascho, and others have found no change in the reaction with any forms of treatment used.

The Wassermann reaction does give strong positive evidence as to the presence or absence of active syphilis. As a rule the diagnosis of lues is not attended with much difficulty, but even in the more open cutaneous manifestations doubtful cases occur where it is of great importance. It is necessary to remember that the reaction gives evidence of syphilis in the body, but not the location of the lesion. A man may have glioma, etc., and also syphilis. In using the test to diagnose obscure conditions, the corroboration of the other tests is of very distinct value, especially where the reaction is partial. In cases with no definite history or distinctive clinical signs a positive diagnosis should be given only when there is little or no hemolysis, and there is a marked sedimentation on standing. If the effort, however, is to exclude syphilis or note the effect of treatment, condition of latency, or cure, a faint reaction should be reported as positive, and should be followed by treatment.

As a clinical test, its greatest importance seems to be as an index to treatment, the serum of luetics being examined in periods of health and in neurasthenic states, and during the acute infections for reappearance of antibodies, and the patient being treated before later serious manifestations appear. The small series in which we blocked out the curve of the reaction under treatment seems to point to need of earlier mercurial treatment, and of more intensive treatment from the first. In obstetrics its value is of immense importance to the child. Pregnant women, if examined and giving a positive reaction, may, if treated carefully, give birth to healthy children, or at least children better equipped for the struggle with life. In the diagnosis of paresis and tabes the complement test seems only to verify the finding of clinical history and cytodiagnosis of cerebrospinal fluid. About 90 per cent. of paretics give reaction, and about 70 per cent. of tabetics.

In the study of the etiological part played in diseases of the nervous system, the reaction was of great importance, especially in multiple sclerosis brain tumor, hemiplegias, epilepsies, and purely luetic troubles. The Wassermann reaction will probably clear up some old problems, and will undoubtedly open up new fields for research.

Excluding leprosy, frambesia, and yaws, we think that a great deal of value is to be placed upon a positive reaction. A negative result is suggestive evidence of the absence of syphilis, but sometimes occurs when active syphilis is present. This might be explained by the fact that the ability of the body to react and form antibodies is exhausted, for it was usually in the old cases of known syphilis that the reaction failed with us.

THE FREQUENCY OF HEPATIC SCLEROSIS IN NONALCOHOLICS.*

By A. L. BENEDICT, A.M., M.D.,

BUFFALO.

The prevalent impression that hepatic sclerosis is quite directly and, at least in a large majority of cases, dependent upon alcoholism, has led to the presentation of the following statistics of individuals carefully observed in private practice and in whose cases the history as to the use of alcohol could be relied upon. The diagnosis rests mainly upon clinical data, especially the alteration in size of the liver, usually in the direction of contraction and the development of small, dendritic dilatations of superficial veins at the diaphragmatic level. Hemorrhoids have not been found characteristic of hepatic sclerosis in either the positive or negative sense and the caput medusæ and ascites are found only in marked cases rarely encountered in private practice among the better class. Gastric catarrh and various digestive disturbances, including back-pressure hemorrhages from the stomach and esophagus, have also been considered in the diagnosis, and have occurred both in alcoholics and total abstainers. The diagnosis has been corroborated by postmortem examination in only about half a dozen of the present series, but, in general, such corroboration has been found so uniformly in other cases as to lead to a considerable degree of confidence in the reliability of physical and symptomatic

*Presented by title to the American Gastroenterological Association, at Atlantic City, June, 1909.

diagnosis. Again, to reduce the personal equation to a minimum, the endeavor has been made to include only well marked cases. These reasons explain the comparatively small number in the series.

The term total abstainer is used in the literal sense except that the bona fide and very occasional medical use of a small dose of an alcoholic beverage has not been counted. The term nearly total abstainer refers to the use of alcohol as a beverage in moderate amount at intervals of weeks or months with years of total abstinence. Total abstinence for years after the ordinary social use of alcohol, not to mention excess, has not been included in either of these categories. The terms, moderate and excessive, so far as possible, have been used as they should be, discounting on the one hand fanaticism and the tendency to minimize a vice.

	Total Abstainers	Nearly Total Abstainers	Moderate	Excessive	Drunkards	Total
Males.....	20	14	105	23	5	167
Females.....	4	9*	4	2	0	19
Both sexes...	24	23	109	25	5	186

Combining the first two and the last two columns, as seems warrantable in a practical etiological study, we have the following:

	Use of Alcohol, None or Negligible		Use of Alcohol, Moderate		Use of Alcohol, Excessive	
	Cases	Per Ct.	Cases	Per Ct.	Cases	Per Ct.
Males.....	34	20	105	63	28	17
Females.....	13	68	4	21	2	10
Both sexes...	47	25	109	58	30	16

In reviewing case notes to secure this series, numerous instances were found of moderate and of heavy drinkers who had failed to develop hepatic sclerosis, even including a few cases examined postmortem. It is obvious that, with the preconceived notion that this disease depends upon alcoholism, confirmation by case histories is easily obtained, since the great majority of persons use alcohol more or less. Just what percentage of all persons this majority constitutes, it is impossible to state, but the most optimistic temperance worker would scarcely place it at less than 80 per cent. The series cited is too small in number of females to warrant conclusions, but it is sufficient for males, and the fact that 20 per cent. of the male cases of hepatic sclerosis occurred in total abstainers or practically such, indicates that such persons are fully as liable to develop this disease as are users of alcohol.

Bearing in mind the fact that hepatic sclerosis may develop without the alcoholic factor, the significance of the history of moderate use of this substance becomes extremely doubtful, especially as many users of alcohol escape. That excessive users of alcohol are especially prone to hepatic sclerosis cannot be denied, but, in such cases, the factors of improper nutrition, syphilis, exposure, and secondary disturbances, may be of much greater importance than the alcohol itself.

Heredity was noted in two sets of father and son, but the alcoholic excess was also noted in both. Syphilis was present in 4 cases, lead poisoning in 1, while several others presented various diseases affecting metabolism, such as heart and kidney disease, splenic anemia, diabetes, etc. No conclusions could be drawn as to the possible effect of tea, coffee, tobacco, excessive use of meat, sugar, or other food. In practically all cases, alcoholic or not, there was a history of protracted, often intermittent, digestive failure of some kind, usually with pretty definite indication of alimentary fermentation or putrefaction, and in many, indican, which has been shown experimentally to produce hepatic sclerosis, was present in the urine. I am therefore inclined to regard the essential cause of hepatic sclerosis as the chemical substances, especially indol and other derivatives from proteins, produced by alimentary fermentation and more particularly by putrefaction in the limited sense.

That alcohol, as such, may cooperate, is by no means denied, but, even in alcoholics, I am rather inclined to regard alcohol as more important as a cause of indigestion, excessive or deficient ingestion and of failure of digestion, and hence of products of fermentation and putrefaction, than as the direct factor. In acute alcoholic attacks, vomiting and diarrheal discharge of enormous quantities of onions, sauerkraut, tainted sausage, and meat stews, are often conspicuous. Even in less acute forms of alcoholism, gastroenteric fermentation and putrefaction are common. On the other hand, total abstainers or temperate users of alcohol, who have hepatic sclerosis, usually give a distinct history of recurrent attacks of dyspepsia, sometimes due to gross violations of the hygiene of eating, sometimes to mental or physical strain, especially occurring at irregular intervals so that the system can not accommodate itself, and sometimes traced back to faulty nursing when an infant.

354 Franklin Street.

*Owing to carelessness in keeping records and the fact that it was more often impossible to draw the line between medicinal and non-medicinal use of alcohol in women, on account of its frequent employment as whisky or brandy at menstrual periods and as beer during lactation, it is probable that several of the nine should be included in the first column.

Subconjunctival Ecchymoses in the New Born.—A. Bonnet-Labordiere refers to the importance of observing the subconjunctival ecchymoses to be seen in the newborn, which are similar in their causation to the hemorrhages found in those who have been strangled. They occur after obstetrical operations, in face presentations, and in normal labors. They are due to pressure on the veins of the neck, and consequent effusion of blood from the vessels, just as these effusions occur in strangling from the pressure of the blood in the veins of the neck and head. They are not due to the length of the labor, but to pressure during delivery after the head has passed out of the vagina, either by the contracting soft parts, or by the hand making traction of the head, and instead of grasping the chin and occiput, pressing on the sides of the neck.—*Journal des Sciences Médicales de Lille.*

Inoculation Against Plague.—The value of inoculation as a plague preventive is demonstrated in the report of a Bombay Bacteriological Laboratory. In Bangalore between October, 1907, and the end of February, 1909, out of 46,986 persons so treated, 34 were attacked by plague and 13 died; among 42,613 persons not inoculated there were 1,798 cases of plague with 1,518 deaths. Major Standage reports that no ill-effects were observed as the result of inoculation. An extensive inoculation campaign was carried out in 28 villages of Kollegal Taluk, in Coimbatore district, 20,108 persons being inoculated as against 31,305 not inoculated. Among the inoculated there were 405 cases and 150 deaths. Among the uninoculated there were 1,180 cases and 921 deaths. The results are even better than the figures indicate, because many of those not inoculated were never exposed to infection. The statistics of one village, Khalispur, are remarkable. Out of a total population of 206, 182 were inoculated in November, 1908. Plague appeared in the following January, and of the 182 persons inoculated one was attacked and died, while among the 24 not inoculated there were 14 cases of plague, and 11 proved fatal.—*The Hospital.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, December 25, 1909.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THE report of Surgeon-General Rixey to the Secretary of the Navy, on the work of the medical corps for the year ending June 30, 1909, has just been published. It makes an excellent showing for the health of the navy, the total number of deaths from all causes in the navy and marine corps, with an average strength of 52,913, being only 305, or 5.76 per thousand. The records of mortality and morbidity for the past few years have shown such a steadily progressive trend toward improvement that it is fair to exclude the possibility of chance and to attribute the bettering conditions to the advance of preventive and curative medicine, and the practical application of the new knowledge by the members of the medical corps. The credit due the medical department for this favorable showing is even greater than it appears, for the service is terribly handicapped by smallness of numbers, only about 208 surgeons being available for the care of 52,913 officers and men in the navy and marine corps, or one medical officer to 254 of naval strength. The conditions in this respect are getting worse rather than better, the ratio reported last year being one medical officer to 210 men.

There are now 51 vacancies in the medical corps and the prospect of filling them and bringing the corps up to its full strength is, under the existing conditions, very poor. No effort has been spared to bring the career offered by the naval medical service to the attention of recent graduates throughout the country by lectures, personal interviews, and the distribution of literature, but in spite of that the number of applicants for admission to the navy medical corps at the end of the fiscal year 1909 was only 29, while the list of applicants for admission to the army medical corps numbered 235. One explanation of this contrast between the two services is to be found in the inadequate compensation that the navy is able to offer candidates for the regular corps during their probationary service in the grade of acting assistant surgeon. Under existing law, the army offers candidates a commission with pay at the rate of $2,100 per year and all the allowances of the lowest commissioned grade, while the navy can offer only $1,400 a year and no allowance whatever. "It is clear," says Dr. Rixey, "that something must be done to correct this great disparity in the relative attractiveness of the army and navy from a financial point of view if existing vacancies are ever to be filled by the sort of men the navy needs." The financial inducement, instead of being less, should be greater than that offered candidates for the army medical corps. To the average man a career in the navy is distinctly less attractive than one in the army. A man with family ties does not contemplate with satisfaction the long periods of separation which sea-service entails, and even the single man who loves his profession and wants to follow the advances in his science is often deterred by the knowledge that much of his life must be passed on shipboard with few and inadequate facilities for practical laboratory work and without the stimulus which association with his fellow workers in civil life gives. The army man, wherever he may be, can have his laboratory and is supplied regularly with medical journals and the newest books, and, in all but the most remote posts, which are now few in this well-settled country, has the opportunity of visiting hospitals and attending medical meetings where he sees and hears all that is going on in his profession. He can also safely contract family ties in the security that he will seldom be separated from wife and children for any lengthy period. To offset these disadvantages of the naval service, the financial rewards should be greater, especially in the lower grades, and the chance of promotion should also be greater. Dr. Rixey insists upon this in his report, and Congress must remedy the defects in the service if the navy is to be kept up to its highest point of efficiency. A powerful and efficient navy without an adequate medical service is inconceivable.

The Naval Medical School continues to bear witness to the wisdom of its establishment. It was founded in 1902 in order to acquaint the young medical officer with the character of his duties and the customs of the service and to train him in the most advanced methods of professional procedure as applied under service conditions before he enters upon his active career, so that he may be prepared to perform the duties of his office efficiently from the beginning. During the past winter the subjects embraced were as follows: Military and naval surgery (including medico-naval and military organization), naval and military hygiene, tropical medicine (didactic and laboratory), bacteriology and pathology, ophthalmology, medical zoology, psychiatry, national quarantine and disinfection, clinical and sanitary chemistry, medical aspect of recruiting, dental emergencies, duties of medical officers, regulations for the government of the navy and military law as applied to the naval service, physical drills, including hospital corps manual, military discipline and signals, etc. The school facilities are designed also to be of benefit to the older officers, who from time to time are in need of opportunity for study under the guidance of experts in various branches of medical science, with particular reference to the latest advances, and to become practically familiar with the newest methods of laboratory technique. These officers attend the regular spring session of the school, which extends over a period

of about two months, the course differing essentially from that pursued during the winter session and planned to give the officers the greatest possible benefit within the time allotted.

The Surgeon-General of the navy is not in accord with the Surgeon-General of the army regarding the Roosevelt physical test, for he seems to look upon it as valuable in showing that the officer who survives the ordeal without permanent injury to heart or other organs has kept himself in good physical condition during the year previous. He admits that opportunities for physical exercise on shipboard are few, for the restricted and encumbered spaces on the upper decks of our modern men-of-war do not conduce to exercise in the open air; hence much time is spent below and a sedentary habit is readily formed. This habit is persisted in by many, if not most of the officers, when on shore duty. Such being the case, it would appear to be a cruelty to subject men so completely out of training to the severe physical strain of the test established by the strenuous and athletic Roosevelt, and not a cruelty only but a direct menace to health and life. If it is necessary to force the officers to keep themselves in physical fitness—and that they should keep themselves fit is self-evident—a better way would be to prescribe a three to five-mile tramp, or a brisk deck walk of an hour and a half every day. If an officer could not or would not obey this rule he could be retired, just as he is now when his heart gives out under the unwonted strain of the annual test. Most sanitary authorities condemn the test as oftentimes dangerous in the extreme, and as in any case inconclusive, since the laziest man may, under pain of retirement, brace himself up to the task and go through it in the blissful assurance that he won't have to walk another step for a year.

A number of other subjects as interesting as those we have touched upon are discussed at length in this report: such are the hospital corps, the nurse corps, recruiting and the physical condition of recruits, the relief work at Messina and that in Adana after the Armenian massacres, diseases affecting especially the men of the navy and marine corps, hospital ships, and the deterioration of health and vigor of the personnel after long service in the tropics.

BORDERLAND CASES OF INSANITY.

Of course it is so obvious as to require but little emphasis to state that insanity is treated now with far greater intelligence than was formerly the case. As a matter of fact, mental disorders were treated not only with an absolute lack of intelligence but with a considerable amount of brutality. A new era in the treatment of the insane was inaugurated by Pinel in France, Elizabeth Fry in England, and Rush and Miss Dorothy Dix in this country. To Miss Dix is chiefly due the honor of first organizing institutions for the insane and of releasing many patients from madhouses and from the strong rooms of poorhouses and from private homes. Dr. Carlos F. MacDonald is mainly responsible for the State Care Act of 1889, and was a pioneer in the most modern methods of treating insanity. There is little doubt that progress has been made in recent years in regarding insanity from a more rational standpoint, although it must still be confessed that even the most advanced psychiatrists of the present day are to a great extent groping in the dark. That is to say that there are many obscure points which require illuminating. Light is breaking in slowly but surely, and it would seem as if the day is coming when our conceptions of insanity will be established upon a thoroughly sound and comprehensible basis. Of the present time it might not be misstating the case, perhaps, if it were said that it is a transition period. Ideas exist in abundance, but as yet they have not been really grasped. The German school is in the front rank from the psychological point of view and Kraepelin is its chief prophet. As Adolph Meyer points out in the New York State Hospital's Bulletin, published in September, Kraepelin has shaken the very foundations of the old structures, and, in the opinion of Meyer, the director of the psychiatric clinic of Munich is to be thanked for the fundamental shaking up of tradition, and for the declaration of independence and of the right of seeing things according to their medical importance. American alienists are following in his wake so far as grouping insanity under headings which commend themselves to their good sense and best judgment is concerned, rather than by classing cases under a set form.

Throughout the civilized world there is a tendency on the part of the medical profession to pay far more attention than has up to the present time been the case, to what are known as borderland cases of insanity. In many large hospitals, wards are set aside in which to place patients who have exhibited mental idiosyncrasies which seem to indicate that they are fit subjects for trained observation. While, however, all are agreed that wise foresight is being shown in watching borderland cases, the question at once arises, What is a borderland case? Meyer answers, "Any case that can be benefited by hospital treatment." This answer is scarcely sufficiently definite, and A. W. Ferris, writing also in the State Hospital's Bulletin, amplifies it as follows: "Any case in which symptoms of commencing mental trouble have been noticed, and which should have a psychiatrist's care. Within the area of the borderland we must include psychasthenia, with its impulsions, obsessions, doubts, phobias, anguish, agitation, delirium of touch; and for practical purposes, we must include all psychoses in their incipiency; we must include psychopathic exaltation and psychopathic depression; constitutional inferiority; disorders in the train of thought, disorders of volition, of the emotions, of memory, of attention, and of personality, whenever such disorders are more than transient." This description is fairly comprehensive, and Ferris advises parents and teachers who detect in a child under their care any such symptoms, or an adult who suffers from the like, to consult a psychiatrist without loss of time.

In 1908 New York State amended the Insanity Law and threw open her thirteen civil State hospitals for the reception, without commitment and

on their own application, of patients whose minds are not so impaired as to render them incapable of forming a rational judgment. It is stated that since the change in the statute, comparatively few voluntary patients have taken advantage of the opportunity to enter the State hospitals, Ferris being of the opinion that the small number is due apparently to want of information or apathy of the general practitioner; to the idea persistent among the laity that real insanity is always marked by violence, and to the feeling that possibly recoverable cases of mental disorder should be kept at home, the hospital being regarded by some citizens as merely a receptacle for the desperate or hopeless cases. There is yet another reason which carries some weight with a large number of people, namely, the slur that is cast upon as individual and even upon his family and relations by the mere suspicion of insanity. This feeling may be due to ignorance or to a faulty comprehension of the matter, but it undoubtedly exists and must be reckoned with.

That certain cases of insanity, especially cases of manic-depressive insanity, would be greatly benefited by early treatment is a proposition that admits of little argument. In fact, perhaps, it would not be going too far to state that all cases of insanity would be better for early treatment. As Ferris points out this is very patent, regarded from an economic aspect. "The average life of the committed patient in the hospital is nine years. It is well known that every early treatment would shorten vastly the duration of the curable psychoses, and would rescue some patients from a nine years' residence. The State is saved from the average expenditure of from $1,288 to $1,472 for every possible nine-year patient who is discharged at the end of one or two years' treatment. All considerations would appear to demonstrate conclusively that the early treatment of borderland cases of insanity is indicated; the difficulties in the way of obtaining such treatment seem to be the unwillingness of parents and guardians of children with mental defects to submit them to inspection of medical men, and the unwillingness of adults similarly troubled to submit themselves to inspection. Further than this, too, it must be allowed that it is extremely hard to diagnose with any degree of certainty a borderland case of insanity. A move in the right direction as regards the treatment of nervous cases is being made in the opening of the Neurological Institute in this city, and particularly so with respect to the announcement that physicians are invited to send patients suffering from nervous, mental, and allied diseases to the dispensary for diagnosis and for treatment, or for admission to the wards. It stands to reason that the general practitioner cannot, as a rule, diagnose mental cases with any degree of accuracy, and therefore the proposal by the trained alienists of the Neurological Institute that he should send his doubtful cases to the Institute for purpose of diagnosis is an excellent one. Unless the physician in general practice will cooperate with the hospitals with regard to possible borderland cases of insanity, little progress can be made, but with such cooperation and with the growing education of the general public as to the importance of treating cases of insanity in their early stages, much good may be done and much knowledge gained. It must be understood that knowledge of nervous diseases in all their manifestations is really what is chiefly needed. After all scientific psychiatry can stand, can possibly walk, but cannot yet run.

THE NATURE OF PSORIASIS.

Two interesting papers concerning the nature and the etiology of this common skin affection were presented before the recent annual meeting of the American Dermatological Society and now appear in *The Journal of Cutaneous Diseases*, Vol. XXVII, No. 326, 1909. The first paper is by S. Pollitzer of New York, who formulates the possible causes of the disease under four headings: (1) It may be due to constitutional changes associated with gout or rheumatism; (2) it depends upon a disturbance of the nervous system; (3) it is a disease depending upon an hereditary predisposition; and (4) it is due to purely local external causes. "Rheumatism" and "gout" have been up to recent times very indefinite and vague terms applied to a number of conditions marked by pains in the joints and muscles, faulty digestion, various disturbances of the renal functions, etc. That these symptoms often occur in the presence of psoriasis is not, of course, to be wondered at; psoriasis is a common affection, and the indefinite symptoms named above and supposedly due to a rheumatic or gouty diathesis are likewise common. There is, however, nothing to show that acute articular rheumatism or typical gout has anything to do with the skin affection in question. That constitutional metabolism has little or nothing to do with the disease is shown, too, by the results of treatment. In America diet, hygiene, and general constitutional régime of the patient is carefully considered in treating the disease, while in Germany little more than local remedies are ever used. Yet, according to Pollitzer, the results of treatment are about the same in both countries: the lesions disappear under the local remedies, while diet and other constitutional treatment appear to have no effect whatever.

Numerous instances are quoted by Pollitzer in which close association seems to have existed between various nervous disturbances, whether of mental or physical nature, and the appearance of psoriasis. Very properly, however, he points out that similar instances could be found with regard to almost any other chronic disease as obstinate and common as psoriasis. The number of such instances, too, is but infinitesimal in comparison with the frequency of psoriasis, and the safest theory in this respect is to assume that the relation of nervous disease and the skin lesions is purely accidental. Heredity is hardly a factor in the disease, for the mere fact that psoriasis frequently appears in several members of the family means very little. Any disposition to accentuate the matter should be tempered by the memory of the many similar occurrences in tuberculosis, and leprosy which, before the specific excitants of these disease were discovered, were pointed out as surely proving the hereditary nature of the affections in question.

The last theory, namely, that psoriasis is an infectious disease of local and external origin appears to be the most acceptable, and this phase of the question is discussed in an able paper by J. Schamberg of Philadelphia. That psoriasis is a constitutional infective disease is hardly reconcilable with its clinical features. It is not attended with any marked disturbance of general health, not accompanied by fever, even in acute eruptive outbreaks, and, indeed, has been very frequently observed in otherwise perfectly healthy individuals. The theory of local origin, on the other hand, is supported by exclusion of other causes and by direct evidence as well. The lesions of the disease enlarge by peripheral extension and often show central healing. A number of instances of contagion have been reported. Schamberg has personally succeeded in producing lesions of the disease by autoinoculation in several patients already suffering with the affection situated elsewhere, these cases being interesting, not so much because of the positive results, but because they seem to suggest that an unknown local predisposition to the affection must have existed in the individuals in question. Failure of other attempts may have been due to the absence of such predisposition in the parts of the skin selected for the experiments.

In general, both authors counsel patience and further experimentation before final conclusions as to the origin of the disease are made. It may be that the most recent experimental methods, such as the use of the higher apes for the purposes of inoculation and the employment of ultramicroscopic examination of the scales and secretions obtained from the lesions may lead to the discovery of the specific parasite; its existence at present can only be assumed because such assumption seems to explain best the clinical phenomena attending the disease.

Suprarenal Extract and Strychnine.

Few drugs introduced during recent years have received such universal acceptance and have come into such widespread use as the extract of the suprarenal gland. Besides its extensive application as a local and general hemostatic, its exceptional power as a vasoconstrictor and cardiac excitant has caused its general adoption as a heart stimulant. One of the most frequent modes of administering the drug for its action on the heart has been in association with strychnine, possibly due to the common practice, when using a new drug, of administering some other medicament of which the action is known and proven, at the same time, in order to insure the desired results. In the *Berliner klinische Wochenschrift* for October 25, 1909, Falta and Jvcovic report a piece of animal experimental work, which in some ways suggests that possibly the combination of suprarenal extract and strychnine is not so happy as at first sight it would appear. Instead of these two drugs being synergic they may be antagonistic. At least in the matter of poisoning, suprarenal extract would appear to be an antidote to strychnine. In the series of investigations reported, frogs and guinea pigs were used. In the frog experiments the strychnine solution was applied directly to the outside of the heart, and when, after twenty to thirty seconds, the organ became tetanic, slowed, and stopped in diastole, suprarenal extract was dropped upon the organ. The result of this was an immediate renewal of contractions. In the guinea pig experiments the drugs were injected under the skin of the abdomen. In each test two animals of equal size were used. To one was given a fatal dose of strychnine, and to the other an equal amount of strychnine and also a dose of suprarenal extract. In each case the suprarenal extract excited a marked protective action against the strychnine, in many instances no symptoms of poisoning appearing after the extract· whereas the control animals died in convulsions within a few minutes. It must not be inferred offhand from the fact that suprarenal extract prevents strychnine poisoning that it of necessity follows that it interferes with the normal physiological action. The inference that it would do so is natural, but the proof is not absolute. A fact of some significance, however, which suggests that this antidotal action is a chemical union of the two drugs, or at least a destruction of the strychnine, is that when they are mixed in certain proportions the mixture, while giving the ferric chloride reaction for suprarenal extract, does not give the sulphuric acid bichromate reaction for strychnine. The entire experiment is of unusual interest and supplies food for thought and for further investigation into the pharmacology of these two cardiac stimulants.

News of the Week.

Bust of Pasteur for the Rockefeller Institute.—The Pasteur Institute of Paris has presented to the Rockefeller Institute for Medical Research of

New York a replica of the bronze bust of Louis Pasteur by Paul Dubois, in recognition of assistance rendered during the recent epidemic of cerebrospinal meningitis which prevailed in France.

The picture here shown, from a photograph of the replica, portrays well the masterful features of this great man of science.

The Third International Congress of Physiotherapy will be held in Paris, March 29 to April 2, 1910, under the presidency of Professor Landouzy, dean of the faculty of medicine of Paris, and the secretaryship of M. Vaquez. An exposition of everything appertaining to physiotherapy will be held in conjunction with the Congress. Correspondence should be addressed to M. Vaquez, Secrétaire Général, 27, Rue du Général-Foy, Paris.

Public Health and Marine-Hospital Service Examinations.—A board of commissioned medical officers will be convened to meet at the Bureau of Public Health and Marine-Hospital Service, 3 B street S.E., Washington, D. C., Monday, January 24, 1910, at 10 o'clock A.M., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service. Candidates must be between 22 and 30 years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. The following is the usual order of the examinations: 1, physical; 2, oral; 3, written; 4, clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate. The examinations are chiefly in writing and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination in the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and, when practicable, candidates are required to perform surgical operations on a cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. Officers are entitled to furnished quarters for themselves and their families, or, at stations where quarters can not be provided they receive commutation at the rate of thirty, forty, and fifty dollars a month, according to grade. All grades above that of assistant surgeon receive longevity pay, 10 per cent in addition to the regular salary for every five years' service up to 40 per cent. after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners, address "Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C."

Medical Council for Canada.—A bill has been prepared in Canada for the establishing of a general medical council whose business will be the establishment of a qualification in medicine, such that the holders thereof shall be acceptable and empowered to practise in all the provinces of the Dominion; the establishment of a register for Canada of medical practitioners, and the establishment and maintenance of a board of examiners for examination and granting of a qualification.

Public Medical Lectures at Harvard.—The annual series of popular lectures on subjects of medicine and hygiene delivered under the auspices of Harvard University will be given on Saturday evenings and Sunday afternoons throughout January, February, March, and April. Dr. Harold C. Ernst, chairman of the committee, announces that further information regarding the course may be obtained by addressing him at the school, 240 Longwood Ave., Boston.

Hospital at Guam Destroyed.—Despatches from Guam state that on December 10 a severe earthquake shock was felt and that the Women's and Children's Hospital was wrecked.

Occupational Diseases.—In an address made before Cornell students on December 14, Mr. F. S. Hoffman, statistician for the Prudential Life Insurance Company stated that statistics showed that occupational diseases were increasing in America.

The Public Drinking Cup.—A new periodical, *The Cup Campaigner* has made its début with the December number. The journal introduces itself as "A militant little paper published at intervals by persons striving to banish that most prolific medium for spreading disease—the public drinking cup; containing authentic reports of the rulings of health officials, the growth of public sentiment through the press, and other developments of the crusade." The editorial offices are at 115 Broadway, and the editor is Mr. Hugh Moore.

Lake Michigan Water.—A sanitary survey of the waters of Lake Michigan along the North Shore, from Evanston to Waukegan is now in progress under the direction of the North Shore Sanitary Association. The laboratories of the Chicago Health Department are making the analyses. Lines of buoys have been set out in the lake, two to five miles from shore, opposite the various pumping stations and sewer outfalls along the shore. Daily samples will be taken during the next three or four weeks for the purpose of ascertaining the extent of pollution of Lake Michigan at these points and to determine the distance from shore to which water supply intakes must be extended to insure a pure water supply.

American "Physician" Wins Case in Berlin.—Dispatches from Berlin tell of the trial of an American "physician" for illegal practice of medicine. The defendant, to whom both a name and an "alias" are given was charged with breaking the German law against unfair competition by posing as an American physician although he was not entitled to do so, and also with breaking another law against using a title without the written consent of the German authorities. He produced a diploma signed by the entire faculty of the "Independent Medical College of Chicago." It was alleged in court that this college was founded some years ago by two men who obtained a State charter, which was afterward annulled by the Illinois courts on the discovery that the purpose of the institution was not instruction in medicine but the sale of degrees. The German judges decided that he was entitled to call himself a doctor and was not guilty of unfair competition.

Pellagra at Peoria, Ill.—The medical officers of the army who were sent to the Illinois State

Hospital at Peoria to investigate the occurrence of pellagra among the inmates of the institution have reported that the disease has probably existed in the hospital for a number of years, although it has not been recognized as pellagra. During the last year the officers found there had been probably 175 cases of the disease in this institution, and from May 1 to August 10, 26 deaths are credited to it.

Red Cross Stamps.—The order excluding letters carrying the Red Cross and other private stamps from the British mails has been withdrawn temporarily, and all American mail bearing such stamps will be delivered promptly. The dead letter office in Washington is reputed to be literally swamped by the number of letters which have been returned there for insufficient postage, due to the senders believing that the Red Cross stamps alone would carry letters, and that the government postage might be omitted.

Dr. Leo Loeb has resigned his position as assistant professor of pathology in the medical department of the University of Pennsylvania to become, in September, 1910, director of a special laboratory for the study of diseases of the skin and of carcinoma in St. Louis.

Obituary Notes.—Dr. Henry Orne Stone of Framingham, Mass., died December 13, 1909, aged 91 years. Dr. Stone as a graduate of Harvard College in 1838 and of the Harvard Medical School in 1841, was the oldest living alumnus of the latter institution and the second oldest of the former. During his earlier years Dr. Stone practised in Boston and Concord, but had resided in Framingham since 1850.

Dr. Charles M. Fisher of Hanover, Kan., died on December 6, 1909, of pneumonia following typhoid fever, aged 35 years. He was a graduate of the Kansas City Medical College in 1903.

Dr. H. R. Elderkin of Cœur D'Alene, Idaho, died recently in his office of heart disease. He was a graduate of the University of Louisville Medical Department in 1854.

Dr. William B. Pusey of Louisville, Ky., died at his home on December 6, 1909, of acute Bright's disease, aged 43 years. He was a graduate of Vanderbilt University and of the University of Louisville in 1887. Dr. Pusey was a member of the Jefferson County Medical Society, the Kentucky State Medical Association, and the American Medical Association.

Dr. James T. Kerrigan of Boston died at Hudson, Mass., on December 9, 1909, from cerebral abscess, aged 35 years. He was a graduate of the University of Vermont.

Dr. John B. Hill of Boston died December 9, 1909, aged 72 years. He was a graduate of the Harvard Medical School in 1853.

Dr. Lafayette Garrett of Galveston, Texas, died December 3, 1909, aged 84 years. Dr. Garrett had practised medicine in Galveston since 1867.

Dr. Chauncey Z. Williams of Covington, La., died December 9, 1909, at the New Orleans Sanatorium following an operation, aged 45 years. He was a graduate of the Medical Department of Tulane University in 1890 and was a member of the St. Tammany Parish and Louisiana State Medical Societies.

Dr. Frank W. Reilly of Chicago died on December 16, 1909, aged 73 years. Dr. Reilly was a graduate of the Northwestern University Medical School in 1861, and was a member of the Chicago Medical Society, the Illinois State Medical Association, and the American Medical Association. He was for years Assistant Health Commissioner of Chicago.

Dr. Henry B. Day of Tacoma, Wash., died suddenly at his home December 6, 1909, aged 25 years. He was a graduate of the University of Oregon in 1905.

Dr. Thomas M. Carroll of Springfield, Ohio, died at his home December 7, 1909, aged 72 years. He was a graduate of the Cincinnati College of Medicine and Surgery in 1874.

Dr. Charles Green of Greenville, Del., died at the Hospital of the University of Pennsylvania on December 13 at the age of 51 years as a result of injuries received in an automobile accident six months ago. He was graduated from Columbia University, College of Physicians and Surgeons, in the class of 1880.

Dr. Frank P. Dundor died at West Leesport, Pa., on December 15 at the age of 61 years. He was graduated from Jefferson Medical College in the class of 1870.

Dr. Irvin Negus Frasse of Monterey, Cal., died December 16, 1909, aged 44 years. Dr. Frasse was a graduate of the University of Pennsylvania in 1890. He practised for several years in Brooklyn before going to California.

(From Our Regular Correspondent.)

SPINAL ANALGESIA—SLEEPING SICKNESS—SURGERY IN TRIGEMINAL NEURALGIA—GENERAL MEDICAL COUNCIL—A DENTAL JUBILEE—OBITUARY.

London, December 3, 1909.

We have had the gratification of a visit from Prof. Thomas Jonnesco of Bucharest and of seeing him demonstrate his method of spinal analgesia, as well as of hearing him address us on the subject. His method is, as you know, to combine strychnine with stovaine, which eliminates the danger of respiratory failure. By his method operations can be undertaken at higher levels than had been supposed—in fact, the strychnine so completely protects the respiratory centers that the analgesia produced by the stovaine may be pushed above their level without arresting or impeding respiration.

The demonstration was given at the Seamen's Hospital, Greenwich, on the 18th ult., when three cases were subjected to operation under Jonnesco's method. One was completely successful, one partially, and one must be called a failure. The first was removal of a mass of tuberculous submaxillary glands. The injection (between the second and third dorsal spines) was followed in about a minute by analgesia up to the level of the forehead and extended as low as the umbilicus and lasted for about an hour. The man walked from the operating theater to the ward and had obviously suffered nothing. In the second case (gastric cancer) the incision was unfelt, but when the stomach was drawn upon there was a groan and he said he felt some dragging inside, not pain. The tumor was found irremovable and the abdomen closed. The analgesia extended from the zygoma above to the thighs below and lasted over an hour. In the other case (mastoid antrum) analgesia was produced from the eyes to the costal margin. On incising the periosteum pain was complained of and the operation completed under a general anesthetic. In all the cases the respiration continued quite naturally.

The address of Prof. Jonnesco was given (in French) the next day at the Surgical Section (R. S. M.) and was illustrated by a number of lantern slides, to show the great extent to which analgesia might by this plan be induced. Most parts could be rendered insensitive by injecting either between the first and second dorsal or between the twelfth dorsal and first lumbar spines.

The work of the Royal Society's commission on sleeping sickness in Uganda was brought before the society on the 26th inst. It was pointed out that for two years

the Administration had been clearing the shores and islands of Lake Victoria. No native had been allowed to live or work within two miles of the shore, except at some cleared landing places, and in the last few months all the islands had been emptied. It was believed until lately that the tsetse retained its infectivity for only forty-eight hours. But experiments now proved that it remained infective for as long as eighty days, and there seems a probability that a fly once infected would harbor trypanosomes for the rest of its life. To ascertain how long flies on the shore continued after the natives had left, some were collected in Baka Bay, where a market was frequented by people from Buruma Island, on which tsetse were present and the natives suffered from sleeping sickness. The landing place was therefore cleared of all undergrowth and very soon the flies disappeared. Other experiments were made with freshly caught flies on the shore after the inhabitants had left for nearly a year, to make sure that the tsetse were no longer infective, as at that time it was expected they would not be. The result showed that the *Glossina palpalis* on the uninhabited shore of Lake Nyanza continued infective for two years after the people had left. Further experiments must be made to determine whether this period may be longer still. The commission refers to two theories which have been offered to account for the facts, viz., (a) long life of the fly; (b) that mammals and birds along the shore had been infected and served as a sort of reservoir of infection. As to (a) the ordinary lifetime of the flies is not known. As to (b) the injection into susceptible animals, from the shore birds and mammals, has hitherto given only negative results.

Mr. Jonathon Hutchinson read a paper at the Medical Society of London on the 22d ult. on the "Operative Treatment of Epileptiform Trigeminal Neuralgia," in which he summarized his experience of thirty operations on the Gasserian ganglion, none of which had proved fatal. Moreover, the deformity usually anticipated had not followed, as he only turned down a small flap from the scalp, removed as little bone as was quite necessary, and did not divide the zygoma. He thought that anesthesia of the skin and mucous membrane following was of little importance, but cranial anesthesia was serious, as the patient was left liable to ulceration from the access of septic dust. Danger to the eye was avoided in his operation, as he left the ophthalmic trunk intact. This plan was carried out in twenty-six out of the thirty cases. In the other four in which the eye and forehead had been left anesthetic some ocular complication happened, but in only one was it serious. It had been said that the cure was not permanent, but in nearly all cases no return was likely. His first case was twelve years ago, and even longer periods had been reported. The great difficulty of the operation was hemorrhage, and the recurrence of this in one case had demanded further operation, and the pressure of the blood clot had led to some oculomotor paralysis on that side.

Dr. Wilfred J. Harris then read a paper on "Trigeminal Neuralgia," in which, after referring to the course, symptoms, diagnosis, etc., he gave his experience as to treatment. During the last twelve months he had seen twenty-nine cases of tic douloureux, and of these he had treated twenty-four by injections of alcohol (80 per cent.). Of these, twenty were so far successful as regards disappearance of pain; two were partial failures. He said that if the needle were pushed in as far as 2¼ inches when searching for the foramen ovale it would be likely to pierce the pharynx, and if any alcohol were injected the patient would recognize it by the smell and the burning at the back of the tongue. It was of no consequence, but must be distinguished from the sensation of trickling along the lower jaw and tongue when the foramen ovale was successfully injected due to the action of the spirit on the lingual and inferior dental portions of the nerve. Sometimes pruritis was complained of in the area of distribution of the nerve after the injection.

Sir V. Horsley said his death rate was 7 per cent. in patients over fifty, but under that age he had not lost one. He held that the mortality as well as so-called disadvantages had been greatly exaggerated; they were more a matter of imagination than clinical fact.

Mr. Ballance said the dangers of operation were diminishing. When possible it was right to try alcohol injection before operating.

Dr. Guthrie said operation should not be resorted to on young subjects.

Dr. Grainger Stewart said alcohol injection had been very successful in the cases in which he had tried it.

Last evening the president, vice-presidents, and Council of the Royal College of Surgeons entertained at dinner representatives of the dentists in celebration of the jubilee of the granting of the charter empowering the college to grant diplomas in dental surgery—the L.D.S. The president, Mr. Butlin, proposing the dental profession, contrasted its condition to-day with that of the early fifties. In this, I think, he hardly did justice to the bygone time, for, in spite of the limited scope of dentistry then, there were a few men in the forefront whose names are familiar to-day and most of them were members or fellows of the college. The president seemed to hope for a time when dental surgery shall not be, as it is, a totally distinct special art—a position he regarded as a danger to medicine. He would have odontology and every other ology connected with medicine to be on the same level and within the same limits of the great art of healing.

After dinner the guests visited the odontological collection lately handed over to the college by the Royal Society of Medicine.

Resuming my notes on the proceedings of the General Medical Council, which continued through the week, I have to report that the number of penal cases was rather high and included several dentists, most of those being charged with disgraceful advertising. Some were excluded from the Register and other cases were postponed until the May session, when they will have to appear again and bring evidence as to their conduct during the interval. This postponement is the only way in which the council can punish a person, except by at once erasing the name from the Register. Where the evidence does not seem to necessitate this penalty, which amounts to professional ruin, the council postpones its decision, and so affords the accused a place for repentance. The cases of medical practitioners accused of "infamous conduct in a professional respect," as expressed in the act, are tried in the same manner, and there were several this session—some being removed from the Register and others postponed until May. All have been previously carefully studied by the penal committee, assisted by the legal advisor, and so none come before the full council unless there appears a prima facie case against the accused. Some of the cases had already been before the law courts, and where a conviction had been the result they offered little difficulty. It might, however, be suggested that the council is scarcely a court of appeal and another question might be raised, viz., if the law has already exacted the punishment of a culprit, how far is it just to impose an additional heavy penalty? for of course the judge in the law court does not take into consideration the "infamous conduct in a professional respect."

The reports of several committees and returns as to examinations were received and considered. With regard to the curriculum the report of the education committee was resumed from the point mentioned in my last, and it soon became obvious that the council did not generally seem disposed to lengthen it. After proposing two and a half years for the final subjects, it was eventually decided that the study of the final group of subjects should extend, after passing in anatomy and physiology, over not less than two years of twenty-four months.

Sir H. Morris carried a proposal that it be referred to the education committee to consider further the place of the preliminary sciences and to frame a pattern scheme of medical education whereby the minimum of the several subjects included in the curriculum can be adequately studied and the requisite examinations passed by the average student within the prescribed period.

The application of the Dublin Hall for recognition of its preliminary examination was refused.

At the concluding meeting on Saturday the report of the anesthetics committee was considered and its conclusions adopted. They were to the intent that the council possessed statutory powers with regard to education to secure that candidates for medical or dental qualifications had received adequate instruction in the administration of anesthetics; that in the public interest the production of unconsciousness should be restricted by law to duly qualified practitioners, provision being made for the instruction of students and for cases of emergency. It was also held desirable that qualified dentists should be authorized to admin-

ister nitrous oxide or other specified substance; that the person giving it should not be the one to operate; that it was inexpedient to create a new penal offense as proposed by the bill now before Parliament as to persons "dying under" an anesthetic, but it was desirable to record such cases by a system of notification similar to that applicable to child birth and to infectious diseases.

Mr. Marcus Gunn, senior surgeon to the Royal Ophthalmic Hospital and consulting or honorary ophthalmic surgeon to a number of other hospitals and charities, died on the 29th of November, aged 59. He studied at Edinburgh and St. Andrew's Universities, as well as in London and for a time at Vienna. He contributed freely to the journals and societies and wrote the article on "Diseases of the Eye" in the operative surgery textbook, edited by Treves.

Dr. Robert Blair, J.P., a leading practitioner in Yorkshire, has died at the age of 62. He was an Edinburgh student and took his M.D. there in 1874. He had been surgeon-captain in the Volunteers and held many offices in the West Riding of the county, for which he was made a magistrate.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

PROGNOSIS OF ALBUMINURIA—MUSCLE TRANSPLANTATION FOR SHOULDER PARALYSIS—PRESSURE AND RELAXATION PAIN IN APPENDICITIS.

BERLIN, November 1, 1909.

THE season of the midsummer rest in the medical life of both the capital and the empire is past. During the past few weeks the scientific societies have commenced their sessions.

Fürbringer delivered a lecture of wide interest before the Society for Internal Medicine. He spoke on the prognosis of albuminuria with especial reference to insurance medicine. In the first place he said that the trifling albuminuria which could be shown only by the most delicate tests were of no influence on prognosis. Here one was dealing with quantities of albumen which might be excreted by entirely healthy men. Furthermore, the physiological albuminurias, which were observed after cold baths, athletic excesses, and strong mental shocks, should not permit the examining physician to consider the patient in the class of poor risks. In the same class belonged the cases of cyclic albuminuria. These cases were differentiated from true nephritis by the absence of high blood-pressure, the absence of albumin on lying down, and from the appearance of euglobulin. Casts and blood might be present in cyclic albuminuria, but fatty granular, waxy, and epithelial casts always indicated a true nephritis. As most of the orthrostatic albuminurias healed perfectly, they should be admitted for insurance. Whether they were taken into the class of high risk must be decided in each case on its merits. Especial attention was demanded by that class of kidney disease in which for years there was an intermittent albuminuria without increased pulse tension or edema. Such cases were also insurable, for the author had seen complete cures in three cases, but they must be put in a substandard class, and the restriction must be put in the contract that if these cases developed a true nephritis the contract did not hold. In true chronic nephritis the applicant was to be rejected. Cases of subacute nephritis must be kept under observation until it became evident which course the disease would follow. A very long period of observation was recommended in such cases, as they might recover after a very long time. When it became necessary to give an opinion on the advisability of the patient with a contracted kidney continuing at work it was a good rule that only those cases were incapacitated for work in whom there was some complication. A year's observation was required before one was able to say that a case of acute nephritis would be quite unable to earn his living.

The first session of the Medical Society on October 27 was favored with a most interesting address and demonstration by Katzenstein on the recovery from paralysis of the shoulder by means of combined muscle transplantation. The case was that of a young laborer who had had an operation for glands of the neck, and as a result his right shoulder was so seriously paralyzed that he could not carry on his work. Examination showed paralysis of the right trapezius muscle. The action of this muscle was very complex, as it had three groups of fibers. The problem was therefore to replace the trapezius by muscles which acted in three directions. In order to accomplish this the following procedure was carried out. The latissimus dorsi of the same side was dissected away in its upper portion, transplanted upward and implanted into the tendon of the trapezius in its lower portion. In order to replace the middle portion of the trapezius a part of the trapezius of the opposite side was loosened and carried around, whereas the upper portion was also supplied by a part of the opposite trapezius. Great care was taken that the attached nerves were preserved and were not injured. The result could be considered to have been ideal. Whereas before the operation the muscle had completely lost all excitability to both currents, afterward the muscle was thoroughly irritable. The shoulder joint was movable in all directions and the patient could perform the hardest labor.

At the same session Blumberg spoke on the pressure and relaxation pain phenomenon in appendicitis. Besides the temperature, pulse, signs of muscle defense, and leucocytosis, Blumberg had found the following signs of great service: If one pressed upon the abdomen and then suddenly relaxed the pressure, the inflamed peritoneum reacted with a sharp pain. It must be observed carefully whether the first or the second pain—the pain on pressure or relaxation—were the greater. The question usually answered itself, for the patient himself informed one of the greater pain. This symptom was frequently to be observed earlier than any other. In acute peritonitis the relaxation pain was more severe than that of the pressure itself, in more advanced disease both pains were equally severe, and finally during subsidence of the inflammation the pressure pain disappeared, whereas the relaxation pain still remained. The sign could therefore be considered as the most delicate of all.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

OUTBREAK OF SMALLPOX IN ONTARIO—OUR SANITARY CONDITIONS IN TORONTO—SEWAGE DISPOSAL BILL—EXPERIMENTAL STATION—AMERICAN FOOTBALL—DOMINION REGISTRATION—ISOLATION OF CONSUMPTIVES IN NEW PRISON TO BE BUILT IN ONTARIO—MILK SUPPLY OF TORONTO AND ONTARIO—RESIGNATION OF LADY SUPERINTENDENT OF THE GENERAL HOSPITAL, TORONTO—PROPOSED REORGANIZATION OF THE UNIVERSITY OF MANITOBA—MEDICAL COUNCIL FOR CANADA.

TORONTO, December 10, 1909.

REPORTS received recently by the Provincial Board of Health announce that after a respite of some months smallpox has again broken out in rural districts of Ontario. In the district of West Zorra there are said to be several cases of the disease, which has been spreading for a few weeks, because it is of so mild a form that until quite recently it had not been diagnosed correctly. A Provincial Board Inspector has been dispatched to the scene of the outbreak to assist and advise the local authorities in coping with the situation. A few cases of smallpox have also been reported from the township of Algooma in Renfrew County.

It seems that even comparatively new countries, as are the United States and Canada, have occasionally the problem of insanitation with them in an aggravated form. New York has its tenement problem and Toronto has its undoubted slums. During the past three or four months the conditions prevailing in certain parts of Toronto have been exposed frequently in the lay press. A large deputation from the Canadian Household Economic Association, at the end of October, waited upon the Toronto Board of Control and made the following requests: A boundary for outside toilets; a civic sanitary household vigilant committee; a woman sanitary inspector for Toronto; a by-law holding landlords responsible for unsanitary conditions surrounding their property, and medical inspection of schools. The president of the deputation declared that the sanitary laws of Toronto are being openly violated and that the association had learned of the most startling unsanitary conditions. Your correspondent can confirm, to some extent, the truth of these statements. He has made a cursory inspection of some of the most notoriously bad districts of Toronto and can assert that in some instances the state of affairs is disgraceful. He is able, too, to speak with some degree of authority, as he is well acquainted with the lowest parts of London and of other

British large cities, as well as with the tenement district of New York. The condition of things in Toronto is wholly due to immigration. Dr. Sheard, the Medical Officer of Health of Toronto, suggests the matter be dealt with at the ports into which the immigrants come, and is of the opinion that the Dominion Government is largely responsible for the present situation.

A sewage disposal bill is now before the Canadian Legislature, which if it becomes law will closely affect Toronto. A clause of the proposed bill reads as follows: "No person shall throw or deposit, or cause or permit to be thrown or deposited, any sewage, offal, or refuse animal or vegetable matter of any kind whatsoever, into any river, stream, or other water, any part of which is navigable or flows into any navigable water." This would seem to mean that either no sewage at all should be deposited into any navigable water or that, if so, such sewage must be very thoroughly treated. The passage of the bill in its existing form would revolutionize the sewage disposal system throughout Canada. The sewage disposal system in Montreal and Quebec is, to put the matter mildly, susceptible of vast improvement. As mentioned in your correspondent's last letter, Toronto has taken steps at last to so dispose of the city's sewage as not to be, as heretofore, a direct menace to the public health. It has been suggested that the Canadian bill is the result of an understanding between the Government of Canada and that of the United States, brought about largely by the efforts of the Hon. James Bryce, the British Ambassador at Washington.

Canadians generally have been intensely interested in the accounts of the deadly nature of the football this season in the United States. The articles which have appeared in the MEDICAL RECORD dealing with the subject have met with general commendation from physicians in Canada, and it is felt that the question should be once more carefully investigated, with the view of modifying the present severity of the game.

Dr. Charles A. Hodgetts, secretary of the Provincial Board of Health of Ontario, has been chiefly instrumental in establishing an experimental station on the outskirts of Toronto. The station was instituted for the purpose of making experiments with water and sewage; that is, to test methods of water filtration and purification and to test some of the modes of sewage sterilization and especially the chemical means of so doing. The building used for these objects contains offices and laboratory and one long room, in which, on either side, are placed large tanks, on one side to be used for experimenting with water and on the other side with sewage. It may be said that establishments of this nature should be found in all large cities, needless to say, supported by the State or by the municipality.

Dr. I. G. Roddick called a meeting of the committee of the Canadian Medical Association on Dominion Registration in Montreal on November 16. British Columbia, Manitoba, Ontario, Quebec, New Brunswick, Nova Scotia, and Prince Edward Island were represented and the following medical councils or provincial examining boards sent delegates to confer with this committee: Nova Scotia, New Brunswick, Quebec, and Ontario. The meeting was convened to consider the resolution passed at the annual meeting of the Canadian Medical Association held in Winnipeg in August, which provided that the Roddick Act be put into force whenever five or more provinces agreed to the provisions of the act. It is understood that the meeting was satisfactory and that steps will be taken to have amendments made to the Canada Medical Act of 1902 at the present session of the Canadian Parliament.

A new departure is to be taken in the designing and construction of the Central Prison to be erected shortly by the Provincial Government of Ontario. The innovation will be the isolation of prisoners suffering from pulmonary tuberculosis. It is obvious that prison life is favorable to the contraction and spread of consumption. An individual suffering from tuberculosis in its early stage or even predisposed to the disease will be extremely prone from his manner of life in prison to develop the malady, and also to spread it. It is, therefore, eminently fitting that consumptive prisoners should be carefully isolated, and the movement in this direction by the Government of Ontario is one worthy to be followed.

The milk supply of every large city, and for the matter of that, of every small town and village, is a subject for discussion in these days. Toronto is no exception to this rule; in fact, the milk question is in a somewhat acute stage in Toronto at the present time. It is stated by many who should know whereof they speak that the milk supply of Toronto, and, indeed, of most parts of Ontario, is not at all satisfactory. Efficient inspection is lacking. The Ontario Government appointed a commission some little time ago to inspect conditions, so far as milk was concerned, in the province, and to report thereon. The commission has ended its tour of inspection and the report will be published in a few weeks, when a certain amount of light will be thrown on the question. There is no doubt, however, that many of the dairy farms are not kept in a proper sanitary condition, and that the milk is not transported in an hygienic manner. The legislation and reception committee of the City of Toronto Council recently decided to apply to the Legislature for legislation providing for a standard for milk and to give the Medical Officer of Health of the city power to inspect dairies outside the municipality. This is assuredly a move in the right direction. It is announced that conditional upon the reorganization of the university making it State controlled and absolutely free from denominational influence, the Manitoba College of Physicians and Surgeons has offered to hand over to the university, without reservation, its fine new medical college, site, and equipment. It has not been decided whether this offer will be accepted. Some of the members of the commission which has been investigating the matter are Catholics and do not seem inclined to agree to a State controlled university.

Miss Snively, lady superintendent of the Toronto General Hospital and head of the training school for nurses in connection with the hospital, which post she has held for twenty-five years, has just resigned.

A special meeting of the Ontario Council of the College of Physicians and Surgeons was held on December 7. There was a full attendance. It has been proposed to create a medical council in Canada, and this proposal was submitted to the Ontario Council by Dr. I. G. Roddick of Montreal, the author of the present Dominion Medical Act. The proposed Federal Council is to have the cooperation and support of the provincial bodies and under its qualification holders thereof shall be empowered to practise in all provinces. A register, boards of examiners, and a status of the profession insuring recognition in Great Britain are provided for, and the powers of the council are defined. It is to be composed of three members from all the provinces appointed by the president in council; a number of members representing each province in proportion to the number of practitioners; one member from each university or incorporated medical college, and one member from each distinct school of medicine. The council will elect officers from its members and appoint a registrar and other officers deemed necessary.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 9, 1909.

A New Treatment for Abdominal Surgical Shock.—J. H. Hopkins gives the following directions which are, he says, especially suitable for shock during the few days or hours following abdominal operations, when the patient is not under an anesthetic. Two skin sutures near the navel are removed and through the opening is inserted a glass tube with rubber to a vessel containing saline at 112°. The tube should be inserted (the wound being held open so that the omentum can be seen) and passed upward beneath the omentum to the posterior peritoneum up behind the transverse mesocolon, getting as near as possible to the solar plexus. About one pint of the hot saline is allowed to flow, and the irritation thus conveyed to the splanchnic nerves and sympathetic ganglia causes a marked rise in vascular pressure by vascular contraction. The tube is removed and the wound covered with gauze and adhesive plaster, with a light abdominal binder to sustain the pressure. In addition, 10 ounces of hot saline are injected into the rectum every two hours. Except the disturbance caused by these measures, the patient is kept absolutely quiet. The author claims that this is the proper way to give saline solution. Really a shock is produced by the sudden pressure of this hot solution on this great and important part of the vasomotor nerve mechanism, but this form of shock is a sudden reversal of the phenomena of surgical shock. When for any reason more than the normal heat or temperature occurs in the body,

it is a function of the vasomotor nerve mechanism to correct it. The elevation of temperature causes irritation of the splanchnic nerves, sympathetic ganglia, and vasomotor centers, and the heart beats faster while the peripheral vessels dilate. The author does not believe that the ordinary methods of using hot saline for shock is aimed at the real cause of the shock. It is of little value as compared with heat and pressure stimulation of the splanchnic nerves.

The Relation of Posture to Human Efficiency and the Influence of Poise Upon the Support and Function of the Viscera.—J. E. Goldthwait presents an elaborately illustrated article on this subject. He says that we should all realize that there is a certain definite amount of energy available for expenditure with each individual; that this energy can be expended in many different ways, but that if it is expended for one thing it is no longer available for others except after periods of recuperation. The form of expenditure, whether mental or physical, is immaterial, and the waste of this energy is not only undesirable, but usually harmful. It is our duty as physicians to show the laity how to get as much out of their available resources as possible. If rightly used, the physical functions will be more perfectly performed, the mental powers will be greater, and the spirit of the individual much finer if expressed through a body properly formed and used. It has caused no surprise to find Washington and Lincoln so poised that there could be no waste from the improper use of the physical frames with which they were endowed. It is our duty to recognize, however, that the types which have been depicted as departures from the best have in them the potential of the finest, and that we can have no higher function than that of making it possible for some of these poor creatures to so live that they or their children may approach more nearly to the standard that it should be the aim of every human being to reach, which when reached must mean a high degree of efficiency of all the elements of the body: the physical, the mental, and the spiritual. The work of the physician must be judged upon the bases of ultimate cure or general efficiency rather than simply the immediate relief of some local lesion. This often represents but the beginning of our work. The paper is illustrated by an interesting series of photographs which bring out the various ideas advanced in the text.

New York Medical Journal, December 11, 1909.

Infantile Scurvy Involving the Hip Joint.—N. Jacobson thinks that this condition is very frequently overlooked and reports two personal cases. Ordinarily, the lower and not the upper end of the femur is the site of this manifestation of scurvy. The epiphyseal areas in children are particularly vulnerable. Following slight traumatisms serious infections are apt to occur, such as acute osteomyelitis or epiphysitis. A study of the clinical history of infantile scurvy teaches that it does not occur suddenly, nor that its course is rapid. Even when in scurvy a traumatism may have provoked a marked aggravation of the manifestations or awakened disturbance at a fixed point, it will be found that the child has for a long period shown evidence of faulty nutrition; that hemorrhage in some form has occurred, either from the gums or bowels, or, still more frequently hematuria, has been evident. In some cases this latter form of bleeding persists for a long time before the characteristic signs of scurvy appear in the extremities. Moreover, with infantile scurvy the symptoms of an infectious condition are absent. The temperature is normal or slightly elevated; when swelling appears it is of limited extent, and never so acute or widespread, nor does the clinical history cover but a few days, as is the case in an infectious process involving a bone or an epiphysis. The changes in the blood are slight in infantile scurvy. There is usually a reduction in the percentage of hemoglobin, and when leucocytosis is present there is an increase in the mononuclear cells. In an infectious disturbance the leucocytosis is produced, and instead of an increase in the mononuclear cells there is marked increase in the percentage of the polymorphonuclear ones. The disease has been mistaken for sarcoma. The scurvy in these cases is more apt to occur between the sixth and twelfth month of life. Practically no cases of scurvy occur in breast-fed children. Treatment is dietetic, and presents no special difficulties. There seems to be in some children a predisposition to scurvy, inasmuch as it has occurred that of twins fed alike one has developed the lesion while the other has escaped. But few cases have followed the use of good cow's milk when used unboiled or but slightly warmed. Long continued boiling seems to be harmful, so far as tending to scurvy is concerned. Grape juice is particularly beneficial, and can be given pure, and the child can take expressed beef juice as part of his diet.

Disguised Starvation and the Reasoning Faculties.—N. Rosewater comments on what he styles an heretofore unrecognized fundamental principle in the physiology of human feeding as distinguished from that of the lower animals and its therapeutic application. The fundamental principle in the physiology of human feeding as distinguished from that of other animals consists in man's inability to appeal from instinct to reason, whose judgments are final, determining why more or less of this and that should be eaten, exercising control over his nutrition, regardless of demand or lack of demand, through mere instinct. Man's judgment, based on reason, weighs the merits and demerits of everything involved in his problem of nutrition; controls his momentary desires and his final acts through giving to appetite fullness and satiety due, but not undue, credence in forming that final judgment. It is not true that appetite is a true and sufficient guide to the taking of nourishment. It is a fundamental principle in the whole social problem of feeding that it is necessary to coordinate the proper relations in the human being of appetite, fullness, and satiety to the faculties of reason, judgment, and will. A sudden or slow cessation of appetite with food reduction soon presents the varied picture of subnutrition, unmasked as it should be, as disguised starvation. Meals should be governed according to the actual needs of the body, and not according to the whims of appetite. Many well-to-do people are apt to be found in this class. Several typical cases are related. On a proper diet of milk and eggs these patients can be brought to appreciate their bodily needs. To save all classes from the results of disguised starvation, the public should be educated to know by tables of normal weight and height, those too far to either side of the normal range, should be taught to use good reason, judgment, and will, so as to get within the normal range by controlling the quantity, quality, and time of their meals. Under the supremacy and influence of man's reasoning faculties, his strong desire for drink and drugs, and his other habits are restrained and controlled, his despondency and other vicious mental and nervous states that inhibit or depress his normal functions are overcome by hope assured, cheerfulness, and other human virtues, substituted as tonics for his vices.

Tuberculosis and Pregnancy.—M. Fischberg reviews this question, and finds that a large experience with consumptives has shown that pregnancy is a very important factor in the origin of tuberculosis in women, especially among the poorer classes, possibly because the latter are more often pregnant than their more prosperous sisters, as well as the overcrowding and poverty in which they live. Indeed, he has been impressed with the fact that a large proportion of male consumptives give a history of comparative health, but that since they "caught cold" or had an attack of influenza some time ago their health has been failing, the cough persisted, and they have been losing weight ever since. With women such histories are less frequently obtained. In a large proportion of married women we elicit a history of a different kind. They have felt comparatively well up till their last pregnancy, when they began to cough, and during the last couple of months of gestation they even expectorated some blood; labor was normal or slightly tedious, and the condition of the newborn infant was not different from the average. During the puerperium, however, their cough was aggravated, they had some fever, nightsweats, and were rather slow in getting out of bed. In fact, they never recovered from the last confinement. Physical examination reveals pulmonary phthisis of any stage. Women coming from sanatoria as arrested cases are not so apt to relapse as men as long as they do not become pregnant. The author has found that in 280 married women who were affected with tuberculosis 107, or 37.4 per cent., stated that they had never had any symptom pointing to tuberculosis till they began to cough and lose flesh after childbirth. Sixty-nine, or 24.1 per cent., had either frequent colds, bronchitis, or even hemoptysis for longer or shorter periods, but got along fairly well until they conceived or were delivered of a child. Ever since, their cough became more troublesome, fever, anorexia, and emaciation came on, and sooner or later they were outspoken cases of the disease. It appears that many cases of phthisis that run a chronic and benign course, including such cases in which the patients cough occasionally for a few weeks or months during the year, expectorate sometimes some blood-tinged sputum in which tubercle bacilli may or may not be detected, and present physical signs of pulmonary tuberculosis, are often awakened from their dormant state by pregnancy. Ordinarily this condition lasts for years without giving the patients much discomfort. Their strength and vitality is, on the whole, not failing to any great extent; their appetite is good, and they keep their

average weight, and during some periods even show a gain. In such patients the recuperative and protective forces are just as great, or even greater, than the destructive. The prognosis is fairly favorable as long as there ensue no intercurrent acute disease which may wake up the latent or encapsulated pulmonary lesion. Generally this occurs after an attack of acute disease, such as pneumonia, typhoid, pleurisy, and especially influenza. In women, in addition to these exciting causes, pregnancy, childbirth, and the puerperium often awaken latent tuberculosis into activity. Artificial abortion is only indicated in cases of laryngeal tuberculosis, and in some cases of tuberculosis which show a tendency to run an acute course, or are complicated with tuberculosis of organs other than the lungs. In the average case the best we can do is to warn our patients of the dangers of pregnancy, and when they do conceive in spite of our warning to pursue an expectant course. In advanced cases there is nothing to gain by abortion, and as the child is usually quite healthy its interests are of primary importance.

Surgical Treatment of Atrophic Rhinitis.—J. G. Wilson finds that many cases of atrophic rhinitis are unrelieved because the underlying condition is not properly searched for. In some an obstructed sinus is a fault, in others there is some overlooked systemic condition. There may be in cases with an atrophy of the nasal mucosa and of the lower turbinates and hypertrophy of the middle turbinate. The opening up of the middle turbinal region and curettage of the ethmoid cells will often bring cure. A series of cases is given which illustrate the author's point. In the author's experience, that the majority of cases of atrophic rhinitis arise from sinus causes. The odor is probably due to secretions which do not have a free outlet, and when the process is of such long standing that the atrophy has involved the middle turbinates and thereby uncorked the sinuses, allowing the free exit of pus, we are apt to find a decided amelioration in the symptoms. Thus, after long years, Nature affects a more or less permanent cure; but this can be greatly hastened by the aid of the surgeon. When surgical treatment fails to relieve it is because the suppurative foci have not all been reached; but it must not be forgotten that the most competent nasal surgeon may at times fail to establish free drainage on account of anomalous positions and unusual formations of the cells, which are not always safely accessible by the intranasal route.

Journal of the American Medical Association, December 11, 1909.

Examination of Stomach Contents.—C. G. Stockton enumerates the indications afforded by examination of stomach contents by means of the stomach tube. The article does not lend itself to condensation very readily, being full of detail. He cautions against attributing too much importance to disturbances of secretion, but says that the greatest importance should be attributed to evidences of disturbances in motion. The diagnosis should not depend solely on the examination, but on the results of this in connection with the symptoms and other facts of the case. Too frequent examinations or those conducted without rule may lead to wrong conclusions. The stomach tube is of the greatest importance in diagnosis, and should be employed more frequently than it is, but it is often useless and sometimes harmful in treatment. At times it is of great value, as in poisoning, gastrectasis, intractable vomiting, and in general for relief of an irritable gastric mucosa.

Trypsin Determination.—G. B. Farr has repeated the experiments of Boldireff on dogs of introducing oil into the stomach to cause regurgitation of duodenal contents and also has made clinical observations on human subjects, using Mette, Volhard, and Gross methods for testing for trypsin. His conclusions are substantially as follows: (1) The duodenal contents may frequently be obtained after the oil test meal, though sometimes there is doubt as to the character of the fluid aspirated. (2) On this account it may be possible to exclude atrophy of the pancreas, but we can demonstrate its presence only under very unusual conditions. Suggestive findings have been obtained in a number of diseases. (3) The observation of Boldireff is of more interest from the point of view of pathological physiology than that of diagnosis, *e.g.* in gastric ulcer and achylia. (4) Volhard's casein method is a delicate qualitative test for trypsin, but needs simplification. (5) The regurgitation of the intestinal alkaline juice induced by oil may explain the therapeutic value of the latter in some cases of hyperacidity.

Pneumectomy.—Willy Meyer has experimented in lung surgery, and reports his success with the aid of differential pressure by a new apparatus devised by himself and brother. In his experimental work on dogs, he adopted the mode of excision and isolation of the organ resembling that now used in appendectomy, namely, isolation of the bronchus; clamping and crushing; ligation and amputation; burying the stump; top sutures. The processes are described in detail. After freeing the bronchus and ligating the severed vessels, a bayonet clamp is placed on the bronchus (the blades being covered with rubber tubing) as near to its base as possible. Above it the bronchus is crushed, usually with Doyen's large intestinal crusher. The remaining fiber sheath is ligated with silk, a clamp placed distally and the bronchus cut off. Before removing the bayonet clamp, or after, according to the case, the bronchus is secured on either side with a pointed forceps, care being taken not to injure any branches of the vagus. The two clamps are pulled on and the crushed part is pushed back into the lumen of the bronchus with anatomic forceps or tucker. Two or three top sutures of silk draw the uncrushed portion of the stump over the buried crushed portion. The sutures should not penetrate to the lumen of the bronchus. When tied, air-tight occlusion results. In case the bronchus divides early it may be impracticable to follow this method, and an emergency method must be used, which he describes and illustrates. The safer and more surgical method, however, is the sewing of the uncrushed portion of the stump over the crushed portion so as to form an air-tight cover. In closing the thorax it must be premised that he avoids, when possible, resection of the ribs and possible injury of intercostal vessels by making a long intercostal incision and separating the ribs with a suitable instrument and working through the opening thus made. Then in closing the wound two or three retention sutures with silk or chromicized catgut surround the two ribs next the incision. Below, the needle enters close to the upper border of the rib which is to be surrounded, and above is made to hug the upper border of the rib adjacent to the incision. The thoracic parieties are closed with continuous layer sutures of catgut. A few retention sutures of silk or catgut approximate the skin wound, which is closed with great care. With the thorax thus closed the pleural cavity is, of course, first filllled with air, which gradually becomes absorbed, the heart, with the opposite lung, is gradually pulled to the opposite side, the diaphragm rises and the thorax flattens out somewhat. Pathological examination of dogs in which the lung was removed in this way showed that no serous effusion took the place of the removed lung. The dogs stood the operation well, and the trial on human beings seems justified. Of the 21 dogs operated on, 17 recovered. In 5 cases of partial removal of the lung there were 4 recoveries, about the same percentage as above. He describes his apparatus for the differential pressure operation at length. It differs from the Sauerbruch or Brauer chambers, though based on their ideas, and both negative and positive pressures can be employed in the same operation. Meyer believes that it will enable us to study pathological conditions in man as well as in animals, and prove the pressures suited for and adapted to the different conditions in many kinds of varying disease of human beings.

Trifacial Neuralgia.—Hugh T. Patrick gives his experience with deep injections of alcohol for the relief of trifacial neuralgia. While not ideal, he claims it is simple, effective in relieving pain, and practically free from serious danger. He uses, as before stated, a straight needle about 10 cm. long fitted with a stylet. The sharp point is used to puncture the skin, after which the stylet is pushed forward, thus penetrating the tissues with a blunt instrument. The needle is introduced at the lower border of the zygoma, the object being to reach the inferior maxillary division of the nerve at its emergence from the foramen ovale (about 4 cm. deep), and the superior maxillary as it leaves the foramen rotundum (about 5 cm. deep). He has abandoned deep injections of the supraorbital branch as being too hazardous. When injection of this branch is needed he uses a "peripheral" injection at the supraorbital notch and in a few cases he has also used a "peripheral" injection at the infraorbital foramen. The solution used is about 85 per cent., alcohol with four grains of cocain to the ounce, and of this about 2 c.c. are used each time. He has abandoned the use of morphine and chloroform in the solution, as also the use of 75 per cent. alcohol for the first injection. The 23 cases reported elsewhere are included in those of which brief detail is given in this paper. In all, more or less relief was secured, though in some the pain recurred. The danger is, he thinks, as nearly *nil* as possible. There have been no fatalities and in only three cases troublesome complications (hematoma, ocular paralysis, keratitis, and corneal ulcer). In a very large proportion there was no return of the pain. Most of his cases have been office cases, and an anesthetic was

rarely needed. There is no shock. He does not claim radical cure, though he thinks that occasionally occurs. A good injection, as shown by marked analgesia, may be expected to give relief for from two to three years, possibly more. He considers that in the majority of cases it is the simplest, least hazardous and best treatment.

American Gout.—R. N. Wilson, Jr., reports four cases of chronic food poisoning in four successive generations of the same family, ranging from the great-grandmother in her eighty-eighth year to a child four years old. That these cases do not stand alone he shows by the record of another case of a girl twelve years old suffering from chronic gouty cold or catarrh. While the case has not been studied to the end, he says there is little doubt in his mind that this child was suffering from the effects of an hereditary appetite and the need of a lessened food supply. Wilson recognizes the danger of too superficial study of such cases tempting the practitioner to term every cold gout, every influenza food poisoning, every ache and pain lithemia, every joint swelling excess of food. On the other hand, carelessness of the significance of signs and symptoms leads to disaster. He says, not without practical interest is the association in at least two of these cases of at least two distinct influences, the toxic and the nervous in the production of symptoms. It shows that not every chronic cough and expectoration can safely be called tuberculosis, that a moderate supply of food may be an under supply or an excess for a given individual, and that many a laryngitis and aphonia may be rationally attributed to the diet and cured by hygienic measures.

The Lancet, December 6, 1909.

Local Sepsis as a Factor in Rheumatism and Gout.—C. W. Wirgman and H. W. Turner pay special attention to the subject of pyorrhœa alveolaris. They have not found a single case of either rheumatism or gout in which local sepsis was not in evidence. Sometimes adenoids and tonsils may be a manifestation of this fact, but pyorrhea is always present. They describe the following types of this lesion: (1) The superficial inflammation around the teeth in ill-kept mouths, which when once restored to a healthy condition can be kept in order by the patient's own efforts. (2) Pockets between the gum and tooth and osteitis of the bony sockets found on examination in apparently well-kept mouths. In nearly all these cases a characteristic odor can be detected. The patients frequently complain of some alteration in or loss of taste and of tenderness and aching of varying intensity, due to exposure of dentine. (3) The genuine pyorrhea, acute or chronic, when pus can be squeezed from around the necks of infected teeth. (4) Dry osteitis, with absorption and recession of gums, which very frequently merges into the third form, and (5) any combination of the foregoing. If in a case with gouty or rheumatic tendencies we can discover these septic conditions early enough, before the general symptoms have developed, we may be able to do them an immense service. If we believe that a diseased joint is due to an organism settling there, there are two future possibilities: (1) That after setting up inflammation the germ dies and there is no further trouble unless a fresh invasion occurs, and (2) that the primary inflammation quiets down because of the attenuation of the virus or from other causes, but the microbe, having effected a lodgment, bides its time and multiplies locally, causing a chronic inflammation. In mixed infections the vaccine treatment does not appear to be of much service. Long-continued treatment is necessary in the cases presenting gum lesions. A cure often results by dropping out of the teeth.

The Influenza Bacillus the Cause of an Epidemic of Bronchopneumonia.—T. S. Wilson and J. Miller had under their care five children in one family, and there were two other children who were in an adjoining house, who suffered from pneumonia at the same time. Ages in the family ranged from one to nine years. Two of the children died. The cases all began with an ordinary influenza invasion, and were followed by pneumonia. Examination of the lungs in the fatal cases showed the usual appearance of a capillary bronchitis and the usual form of bronchopneumonia. Stained sections showed bacilli similar to those cultivated from the cases, in the alveoli. Pathologically, the chief points of interest in the cases were the epidemic nature of the disease and the occurrence of the influenza bacillus as the only organism present in the lung in one of the cases. From the occurrence of the cases at one and the same time, and the fact that cultures of ordinary media failed to show any growth in the other fatal cases, one may conclude that the causal germ in all the other cases was the influenza bacillus. The occurrence of this germ in bronchopneumonia has long been recognized, and the fact that not infrequently it is the only organism present in the lungs has been emphasized by Fraenkel. The main point of interest in the present instance is therefore the occurrence of the influenza bacillus as the cause of a number of cases of bronchopneumonia arising so obviously in connection with one another as to warrant the term epidemic. There was nothing particularly noticeable in the clinical course of the cases. The dullness and tubular breathing were not so marked as in pneumococcic pneumonia. The children were all attacked suddenly, and the course of the pneumonia in each was severe.

Surgical Treatment of Puerperal Pyemia.—Two case histories are detailed by E. Michels, one dying and one recovering. The object of the paper is to describe and comment on the plan of ligaturing the deep pelvic veins with reference to checking the spread of infection when one has laid hold of the patient. Many questions concerning this plan of treatment are still undecided. As a working program the author advises the following: (1) In cases of puerperal pyemia an attempt should be made to localize the septic process by ligature of the great pelvic veins, ovarian and internal iliac, and possibly median iliac. (2) The very acute cases of puerperal pyema are not suitable for this operation, but the more chronic ones, which are due to an infection by an attenuated virus promise a good success, provided the operation be not deferred too long. (3) The veins should be exposed by the transperitoneal route in preference to the retroperitoneal or vaginal. (4) All the four great venous trunks should be exposed and examined, but isolation and ligation seem necessary only for those veins which are found diseased. (5) Further experience is required to decide whether the results can be improved by excision of the venous trunks and plexus in preference to simple ligature.

Berliner klinische Wochenschrift, November 22, 1909.

Relation Between Pregnancy and Diabetes.—Neumann discusses the serious results following the association of pregnancy and diabetes, and concludes his paper with the following statements: Though diabetes mellitus and pregnancy do not often occur together, considering the unfavorable course taken by diabetes in women of childbearing age, it is necessary to treat all possible cases prophylactically. Diabetic maidens must not be allowed to marry. Married diabetic women must be prevented from conception. Diabetic women who have become pregnant, and pregnant women who have become diabetic, or are excreting a fermentable sugar, must, as early and as long as possible, be under careful medical supervision and regulation of diet. We should resort to operative procedures only in the presence of obstetric indications for them, without regard to the diabetes mellitus.

Influence of Athletics on Lung Capacity.—Du Bois Raymond has studied the pulmonary vital capacity in a series of athletes and non-athletic university students, and finds that the lung capacity of the athlete averages about 330 c.c. greater than that of the unathletic students. The greatest difference is among singers and the smallest among swimmers. The average improvement in breathing of 330 c.c. in an average capacity of 4000 c.c. means a respiratory improvement of about 8.2 per cent.

Deutsche medizinische Wochenschrift, November 25, 1909.

Serumtherapy for Asiatic Cholera.—Kolle reports on the use of the cholera serum made in Berne in the recent epidemic of cholera in Russia. Of 149 cases in the severe algid stage of the disease, 56 died, or a mortality of 37.5 per cent. Of 25 cases of medium severity all recovered. Of 13 mild, though definite, cholera cases all recovered. All agree that the administration of even very large quantities of serum in cholera can do no harm. He concludes by saying that the outlook for cholera cases even in the algid stage, when treated with cholera serum, especially in combination with large amounts of saline infusion, is not especially bad. However, we cannot speak of the serum as a sure cure in the algid stage of the disease. The series of observations is too small to make it possible to draw any comparison between the results of cholera serum treatment with those of diphtheria antitoxin.

Albumin Tests in Practice.—Engels has made a comparative study of the various clinical tests for albumin in the urine, especially with reference to adding acid before or after boiling in the common test. He concludes that in practical work the best results are obtained by adding diluted acetic acid after boiling, and especially so when only the upper half of the urine is boiled. It is strongly recommended to compare this test with the acetic acid, potassium ferrocyanide test, as this is easily done, and errors can be corrected. On the contrary, all tests in which acid is added first should be abandoned.

Book Reviews.

PEDIATRICS. Edited by ISAAC A. ABT, M.D., Assistant Professor of Medicine (Pediatrics Department), Rush Medical College. With the collaboration of MAY MICHAEL, M.D. ORTHOPEDIC SURGERY. Edited by JOHN RIDLON, A.M., M.D., Professor of Orthopedic Surgery, Northwestern University Medical School, with the collaboration of A. STEINDLER, M.D. Vol. VII. of the Practical Medicine Series. Chicago: The Year Book Publishers, 1909.

IN this small volume of 233 pages over three-quarters of the space is given to the subject of pediatrics. Important facts in connection with hygiene, dietetics, and the diseases of the gastrointestinal tract, and some interesting points in regard to the etiology of scarlet fever, whooping cough, and rickets have been mentioned.

In the part devoted to orthopedics the principal subjects considered are the diseases of the hip-joint, spine, knee-joint, and ankle and foot. Space has also been given to the discussion of the results of tendon transplantation in the after treatment of infantile paralysis.

MANUAL OF THE DISEASES OF THE EYE. For Students and General Practitioners. By CHARLES H. MAY, M.D., Chief of Clinic and Instructor in Ophthalmology, College of Physicians and Surgeons, Medical Department, Columbia University, New York, 1890-1903; Attending Ophthalmic Surgeon to the Mt. Sinai Hospital, New York; Consulting Ophthalmologist to the French Hospital, to the Gouverneur Hospital, to the Red Cross Hospital, and to the Italian Hospital, New York. Sixth Edition, Revised. With 362 Original Illustrations, Including 22 Plates, with 62 Colored Figures. New York: William Wood & Co., 1909.

THE fundamental facts and all the essentials of ophthalmology are presented in this book in a concise manner. The common diseases which the practitioner is frequently called upon to treat are discussed with some degree of fullness. The rarer conditions and uncommon affections, which are of interest chiefly to the specialist, have been discussed with a few lines. The general arrangement of the book is the same as in previous editions. The first three chapters are devoted to the technique of the examination of the eye, and the last chapter to the discussion of ocular therapeutics. The intervening space is given up to the consideration of the diseases of the eye, arranged according to the part affected. Some alterations have been made and paragraphs have been added on such subjects as transillumination, the conjunctival tuberculin test, and cerebral decompression. The volume has been kept up to date, but has not been increased in size. The necessity of six editions in nine years speaks well for the popularity of this book.

PHYSICAL DIAGNOSIS. By RICHARD C. CABOT, M.D., Assistant Professor of Medicine in Harvard University. Fourth Edition. Revised and Enlarged. With five plates and 240 figures in the text. New York: William Wood & Co., 1909.

THIS volume in its earlier editions is already so well known that it is superfluous to describe its contents, as it is certainly the most popular work on this subject with the American student. Its clearness, brevity, and completeness have already won for it a place among the leading text-books of the day. The present edition has been changed in but a few minor details from the last one, which appeared in 1905. A few words have been changed and a few paragraphs rewritten. The main difference noticeable is a distinct improvement in the pictures, which are far ahead of those in the last edition. This is especially noticeable in the cuts of blood cells, which in the present edition are as good as could be desired in black and white pictures. The former editions of this book have won for themselves well deserved popularity, and the present one can do nothing less than maintain for it its present enviable position.

IMMUNITY AND SPECIFIC THERAPY. By W. D'ESTE EMERY, M.D., B.Sc., London Clinical Pathologist to King's College Hospital and Pathologist to the Children's Hospital, Paddington Green; Formerly Assistant Bacteriologist to the Royal Colleges of Physicians and Surgeons, and Sometime Lecturer on Pathology and Bacteriology in the University of Birmingham. With Illustrations. New York: Paul B. Hoeber, 1909.

THERE already exist several excellent works in German dealing exhaustively with the subjects to which the present volume is devoted, but this is by far the most comprehensive presentation of these matters available in English. In fact, it is astonishingly complete, and even very recent publications have been incorporated in its pages. In general nothing but praise can be expressed regarding it, the only possible alteration that sugggests itself being that for the average reader it might facilitate rapid orientation in the ways of thought and general conceptions involved if the full explanation and discussion of Ehrlich's theories and their ramifications were introduced somewhat earlier in the volume. The method of attacking the problem of logically presenting the mass of theoretical material concerned in the building up of the present views on immunity and allied phenomena is so largely a matter of individual opinion, however, that the above is not to be regarded as a criticism. The author has wisely abstained for the most part from partisanship, and where conflicting views exist has contented himself with stating the opinions of the different observers fairly and impartially. He follows the theorists into all the remote provinces of physical chemistry that modern serological research has invaded and explains very clearly the rather abtruse principles oftentimes involved, such, for example, as Guldberg and Waage's law of mass action, Arrhenius and Madsen's theory of the toxin antitoxin reaction; the laws of surface tension as applied to agglutination, etc. In the latter connection some interesting suggestions are made in regard to the agglutination of the red blood corpuscles, and especially the rouleaux formation taking place in shed blood. Some previously unpublished researches of Wiltshire are described which appear to indicate that this phenomenon which obviously has some resemblance to agglutination may be due to the development of a substance in the serum at the moment the blood is shed, or to a physical change in the corpuscles themselves. The colloidal theory of antibodies is the subject of an especially suggestive chapter, and the author inclines to accept this hypothesis as having most evidence in its favor. In speaking of the ophthalmoreaction with tuberculin, like many other observers, he expresses the opinion that even when the eyes are healthy the risk involved in applying the test is ordinarily not worth running. The book may confidently be recommended as the most modern and complete of its kind in the English language, and it will doubtless find a wide circle of readers.

A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE. By ARTHUR R. EDWARDS, M.D., Professor of the Principles and Practice of Medicine and Clinical Medicine in the Northwestern University Medical School, Chicago. New (Second) Edition, Thoroughly Revised. Octavo, 1,246 pages, with 100 engravings and 21 full-page plates in colors and monochrome. Philadelphia and New York: Lea & Febiger, 1909.

DR. EDWARDS' book contains over twelve hundred pages, and forms a complete treatise on the subject of the practice and principles of medicine, nervous diseases being included within its scope. In arrangement of the subject matter it follows the most recent standards, specific infections being considered in the first part of the book, anatomical divisions being followed for the classification of other affections. The articles are very practical, the immediate demands of the clinic and laboratory being given precedence over theoretical discussions of the diseases considered. This is especially true of the sections devoted to therapeutics. Thus, the treatment of typhoid fever is given in complete detail, with illustrations of practical arrangements for applying hydrotherapy at the home of the patient, with numerous prescriptions and hints as to diet, nursing, management of convalescence, etc. Throughout the book the logical in therapeutics is laid stress on in distinction to purely empirical methods.

The sections on diagnosis are made very valuable by well-constructed tables of comparative signs and symptoms that should prove useful in differentiating similar affections. Illustrations are used not so much to fill the book with pictures, but to elucidate the contents; thus, blood diseases are illustrated by well-executed colored plates that take the place of lengthy descriptions of the various cellular types met with. Retinal findings in more important diseases are given; numerous engravings picture bacteriological and clinical findings, such as temperature charts, facies, the appearance of tubercle bacilli in sputum, of diphtheria bacilli in pure culture, etc.

Advantage has been taken of the reissue of the book to include the results of the most recent advances in medicine. Cardiac neuroses and arrhythmias are treated at length, Flexner and Jobling's results in the use of antimeningitis serum are noted, "bacilli carriers" are commented upon, and the recent discoveries in the etiology of syphilis and in the diagnosis of tuberculosis are given due attention. In general, the work forms a well-balanced treatise on the subject of medicine, fulfilling all the demands of the student and practitioner.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held November 21, 1909.

THE PRESIDENT, DR. H. SEYMOUR HOUGHTON, IN THE CHAIR.

Election of Officers.—The following officers were elected to serve during the ensuing year: *President,* John E. Weeks; *First Vice-President,* James F. McKernon; *Second Vice-President,* William L. Stowell; Secretary, John Van Doren Young; *Assistant Secretary,* J. Milton Mabbott; *Treasurer,* Charles H. Richardson; *Censors,* Linnæus E. LaFétra, Brooks H. Wells, and H. Seymour Houghton.

Report of the Committee on Legislation.—Dr. E. ELIOT HARRIS reported that about 225 so-called medical bills were introduced into the legislature of 1909, and the following had been enacted into laws:

1. An act to authorize and provide for the erection and maintenance of an additional public hospital between Twentieth and Seventieth streets in the city of New York.

2. An act to amend the Greater New York charter, authorizing the department of health to assume exclusive charge and control of hospitals for the treatment of contagious, pestilential, or infectious diseases.

3. An act to amend the Greater New York charter in relation to ambulance service. The law creates a Board of Ambulance Service, the Commissioner of Police to be the president, the Commissioner of Public Charities to be the secretary, and the other member to be the president of Bellevue and allied hospitals.

4. An act to confer certain rights on the municipalities of Nassau County in regard to the water in such county forming part of the water supply of the city of New York.

5. An act to amend the public health law in relation to the quarantine commissioners and the health officer of the port of New York, and repealing certain sections relating to the quarantine commissioners. This act abolishes the quarantine commissioners and confers their duties upon the health officer of the port.

6. An act making an appropriation for the New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis.

7. An act to provide for a tuberculosis hospital at the New York Soldiers' and Sailors' Home at Bath, and making an appropriation therefor.

8. An act to amend the public health law in relation to the establishment of hospitals or camps for the treatment of pulmonary tuberculosis.

9. An act to amend the county law in relation to the establishment and maintenance of county hospitals for the care of persons suffering from the disease known as tuberculosis.

10. An act in relation to the insane, constituting chapter twenty-seven of the consolidated laws.

11. An act to authorize the State commission in lunacy to proceed with certain improvements at the State hospitals for the insane.

12. An act making appropriations for construction, additions, and improvements at the State hospitals for the insane.

13. An act making appropriations for repairs, renewals, and betterments for the several State prisons, the Matteawan State Hospital for Insane Criminals, and the Dannemora State Hospital for Insane Criminals.

14. An act authorizing the sale or exchange of the rifle range at Creedmore for lands to be used as a site for the Long Island State Hospital, and reappropriating moneys heretofore appropriated for the Long Island State Hospital.

15. An act making appropriations for the Eastern New York State Custodial Asylum. This bill appropriated $494,000, of which the Governor vetoed over $50,000.

16. An act to provide for the management of the Eastern New York State Custodial Asylum, to be known hereafter as the "Letchworth Village," and for the admission and control of inmates therein.

17. An act to enable the Medical Society of the State of New York to alter the time and place of holding its annual meeting by a two-thirds vote of all the members of the house delegates present at any annual meeting, provided notice of such change be given at the previous annual meeting.

Reports of the chairmen of the various committees were received and action on the amendments to the constitution and by-laws was taken.

The Micromotoscope.—Dr. ROBERT LINCOLN WATKINS said that there had been many reports emanating from Paris that M. Commandon had demonstrated before the Academy of Science microscopic moving life for the first time. Photographing microscopic moving life was conceived by Dr. Watkins fifteen years ago, and demonstrated with an apparatus of his own construction in 1897, and his work was published in the *Scientific American,* the issue of July 31, 1897. Dr. Watkins presented a portable machine for taking the pictures for use either in the laboratory or the house of the patient. He showed his micromotoscope and moving blood-cells, a rotifer in water, and germs in putrefactive urine.

A Case of Fibroma Molluscum.—Dr. WILLIAM S. GOTTHEIL presented a man, sixty-eight years old, whose affection dated from his earliest childhood. At first the tumors were few and small, but they had increased in number very rapidly, especially during the past few years. The entire surface of his body was studded with an immense number of tumors of varying sizes and shapes; a conservative estimate of their number was over one thousand. They were of two distinct types, with combinations of the two. There were flesh-colored or faintly pink circumscribed tumors in the deeper layers of the skin, extending into the subcutis. As these enlarged they became prominent, and finally pedunculated so that, on the back, for instance, they were as large as a small egg, and with a long, flexible pedicle. There were also multitudes of tumors not palpable on superficial touch. They showed a circumscribed bluish discoloration of the skin, and deep palpation revealed the presence of an oval or circular distinctly margined hiatus in the dermal connective tissue. As these latter lesions grew in size the soft underlying tissues were protruded into a visible and palpable soft bluish tumor. Many of the large tumors were compound, with secondary tumors in the skin overlying. The mucosæ were free, as well as the genitals. There were no subjective symptoms referable to the disease. The case was one of a mixed type; in addition to the ordinary soft fibromata there were multitudes of phantom tumors of the Von Recklingshausen type, in which atrophy of the connective tissue elements of the cutis permitted the mechanical pressure obtrusion of the softer underlying structures.

A Case of Agyria.—Dr. WILLIAM S. GOTTHEIL presented a man, thirty-seven years old, who acquired syphilis fifteen years ago. He showed the scars of old ulcerative lesions on the face, neck, trunk, and limbs. His eyelids and nares were deformed; columella and cartilaginous septum nasi were gone; the soft palate and pharnyx were deformed and cicatricial; the tongue was thickened and indurated with epithelium irregularly hypertrophic (lingua geographica). He had trachoma, diffuse opacity of the right cornea, and the right iris was smaller than the left, but movable. He had a chronic laryngitis; his general health and nutrition, however, were good. The entire

skin, with the exception of the palms, soles, and genitals, and all the visible mucosæ were stained a more or less deep steel gray color. This was most marked on the face and neck, where the color was distinctly steel black. The scar tissue marking the old ulceration sites was hardly stained at all, and the circular and oval cicatrices were prominently white. The skin of the trunk and limbs was ash-gray in color. The cicatricial areas were unpigmented. The backs of the hands were dark gray, but the palms, though showing old cicatrices, were approximately normal in color. The scleræ were distinctly blue-gray. The entire palatal vault and the fauces were steel-gray in color, and the swollen tongue was grayish-pink wherever the hypertrophic epithelium permitted the tissue to be seen. The history explained the dermal condition. Some ten years ago, during the earlier stages of his luetic infection, he suffered from persistent ulcerative throat trouble, of which the cicatricial changes in the tongue, palate, and fauces were evidences. For seven years or more he was in the habit of applying a 10 or 15 per cent. solution of silver nitrate freely to his throat, often using it several times a day for weeks at a time. Undoubtedly, large amounts of the drug were gradually swallowed. Two years ago he noticed the gradual darkening of the skin of his face. He believed that this had been gradually getting lighter during the last year, but nothing of the kind was apparent to those who had had him under more or less continuous observation during the past six months.

A Case of Lepra Maculosa.—Dr. GOTTHEIL also presented a man, twenty-nine years old, an inhabitant of this country for eight years, who was admitted to the City Hospital in the fall of 1909. Three years ago he noticed a nervous tingling in the fingers of his right hand; about one year ago the fingers of that hand began to get "clawed," and the hand began to get thin. Some eight months ago he noticed certain spots on his body. When admitted to the hospital there were several large round, slightly brown circular areas of skin on his trunk and buttocks. Some of these were six inches and more in diameter; their color was faint, and around them was a band one-half an inch in size, of apparently normal skin, and then another faint brown band. These, though still visible, had markedly faded away during the time he was under observation. The skin of the right forearm was markedly atrophic and wrinkled; there was great atrophy of the intermetacarpal muscles of the right hand, with contracture and incomplete anesthesia of the pigmented areas. There was a distinct thickening of the right median nerve. There was a slight tuberculation of the forehead. The specific bacilli were demonstrated by scrapings and biopsy. The internal organs were normal, and his general health was perfect. There had always been cases of leprosy in the skin wards of the City Hospital since 1883, and the routine treatment was chaulmoogra oil and its derivatives. He had never, however, been able to convince himself that it had had any effect upon the disease. The patient had been under the nastin treatment, which had been recommended of late years, for several months, getting the contents of one ampulla, two grams every fifth day. Some of the symptoms had improved a great deal. The forehead tubercles had retrogressed, so that they were hardly noticeable, and the color of the pigmentation had become markedly lighter. In another and more advanced case that had been under the same treatment, there were also evidences of improvement. Without expressing any opinion at all as to the efficacy of the treatment, he believed it was worthy of further trial. The perfect general health of this patient, the entire absence of any lesions which might possibly be a source of infection, and the possibility that the disease process might remain stationary for years, emphasized the correctness of the policy of the New York Board of Health in regard to it.

Bier's Hyperemic Treatment in Surgery.—Dr. EDWARD ADAMS read this paper, demonstrated the treatment on patients, and showed the instruments used. He said that, as a result of modern study and investigation, the former views regarding inflammation had undergone a remarkable change; they now looked upon it as nature's most powerful agent to protect the tissues from the ravages of bacteria and their toxins. Hyperemia was Nature's greatest therapeutic agent. Prof. A. Bier of Berlin had been using this treatment for the past eighteen years in his clinic with success. In active hyperemia the fluid and formal elements were kept in active motion in the blood stream, while in passive hyperemia they were allowed to escape more or less from the tissues. Hyperemia possessed a great many properties: (1) Power to diminish pain; (2) bacterial action; (3) absorptive properties; (4) solvent action; (5) nutritive power; (6) suppression of infection. Hyperemia might be produced in three ways—by means of an elastic bandage or band, by cupping glasses, and by hot air. The first two produced venous or passive hyperemia, the third arterial or active hyperemia. Obstructive hyperemia was produced by means of a thin soft rubber elastic bandage; when applied moderately tight around a limb the pressure was evenly distributed and should not cause any uncomfortable feeling, and there should be no pain. At all times one should be able to feel the pulse below the site of the bandage. The two cardinal rules to follow were, absolutely no pain with the application of the bandage, and the pulse at all times must be felt below the bandage. Where the conditions required a long continued hyperemic treatment the extremity should be raised on pillows or by a suspension splint. In acutely infected joints the sooner the bandage was applied the better. Hyperemic treatment had made the large incision unnecessary in the treatment of phlegmon, cellulitis, and like conditions. Drainage and gauze packing could also be dispensed with. In acute osteomyelitis the elastic bandage applied early enough might avoid necrosis of the bone. In cases of acute gonorrheal arthritis the sooner the bandage was applied the better.

It was in tuberculosis of the bones and joints that Bier first used venous hyperemia and, in common with all conservative methods for treating tuberculosis of the bones and joints, it required time and patience. The contraindications for Bier's hyperemic treatment were (1) Amyloid degeneration of the lung; (2) advanced tuberculosis of the lung; (3) faulty position of the parts; (4) large joint abscesses. Each case should be treated individually and the bandage applied according to the indications. In cases of extensive effusion into a joint, aspiration with the injection of iodoform glycerine could be used with benefit. In the ankle, elbow, and wrist joints about 75 per cent. of the cases gave a cure with a good functional result. For mechanical reasons the hip joint could not be treated. Obstructive hyperemia would not cure every case of tuberculosis of the bones and joints, but it was by far the best aid to conservative methods that they possessed at present; it reduced the amount of pain; it was simple, inexpensive, and could be used with the least possible discomfort to the patient when properly applied. In cases where obstructive hyperemia by the elastic neckband was required, the veins should be compressed so as to increase the quantity of blood to the head, but it should not interfere with the patient's ability to sleep, eat, or drink. In diseases of the testicle, rubber drainage tubing of medium size was wound around the scrotum on a layer of cotton batting. This method was used chiefly in cases of tuberculosis of the testes, sinuses, and epididymitis. Hyperemia was also produced by cupping the part to be treated. In using vacuum appliances a mechanical effect was produced in addition to artificial hyperemia. By placing a suction glass over a diseased area which pre-

sented a sinus, the pus with the bacteria was aspirated from the depth, and often necrotic tissue or small sequestra were brought to the surface. The following rules could be followed as a routine: (1) Strict asepsis should be employed. (2) The application should not cause pain. (3) The cups should be sterilized after each and every treatment. (4) Suction should be intermitted and the cup remain on for five minutes and off for three minutes. (5) The rim of the cup should be annointed with sterilized vaseline. (6) If an abscess was present it should be evacuated by a small incision. (7) One treatment should last forty-five minutes. In treating furuncles or carbuncles the cup must be of sufficient size to extend beyond the inflammation; if applied early it would usually prevent suppuration. Perhaps in no class of cases had suction hyperemia been used to better advantage than in acute mastitis. The treatment started as soon as the first symptoms appeared, and often saved cases from reaching the second stage. In abscesses on the face the treatment should be employed several times a day, and the earlier the case was treated the better would be the results. In treating mastitis it was absolutely necessary to have glasses of various sizes on hand, so as to select the exact cup needed. In tooth fistula, after dead bone, carotic teeth, or root of a tooth had been removed, the suction glass, if applied as described, might bring a sinus to a close without any disfigurement. Excellent cosmetic results had been obtained in four cases that had come under his care.

For the production of hyperemia by means of hot air, the heat was applied chiefly by means of hot-air boxes or chambers. The most useful hot-air boxes were wooden chambers of simple and inexpensive construction, which were provided with a lid showing one or two openings for the reception of the limb. The guides for the proper degree of temperature were: (1) No pain nor annoyance from the heat. (2) All openings must be airtight so as to prevent the hot air escaping and burning the skin outside. Fractures, both recent and old, were greatly benefited by arterial hyperemia. Active hyperemia had given very good results in chronic ulcers. Moderate baking for from one to two hours per day hastened cicatrization. Tuberculosis of the joints was a positive contraindication. Hyperemic treatment was not a panacea for all surgical conditions, but was merely a therapeutical agent to be used where it was indicated. The dangers attending its use were the injury that an overdose would do and the futility of homeopathic doses.

Dr. Willy Meyer said that it should be absolutely understood by the medical profession as a whole that the Bier hyperemic treatment was by no means a panacea. It was merely an additional therapeutic resource on a physical basis, and, if properly understood, he was sure it would be so considered. Dr. Meyer thought from what he had heard and seen in the course of the last few years, it was a mistake to call this "Bier's hyperemic treatment"; it would be better to call it the "more blood treatment." If called the more blood treatment, one could easily understand or comprehend what was really meant when this treatment was employed. By the use of this treatment it had been proven by Bier that his explanation of inflammation was the correct one; namely, that inflammation was the fight of nature against an invading foe; the complex of symptoms should therefore rather be favored than fought against. The more blood to a part the more would also the function of that part be preserved. Take, for instance, a deep phlegmon, involving the deep flexors of the forearm and hand. In former years one was perfectly satisfied with bringing the patient through such a dreadful disease with as useful a hand as possible, with usually a very stiff wrist, unless the phlegmon was treated surgically during the very first hours of the condition. To-day the Bier treatment had changed matters very materially. The results of the more blood treatment showed that doctors should work more with it; but he supposed they did not do so because it required much time, much care, and much experience to get satisfactory results. However, some men abroad had taken this treatment up in large measure. It had been shown that the application of the elastic bandage proximately to the seat of the disease produced the same results as the hot air, viz., artificial arterial hyperemia. Therefore, the hot air was used in preference to the elastic bandage.

Bier had advised against the use of hot air in cases of acute infections and of tuberculosis; yet there were men abroad bold enough to use it, and with success, for instance, in cases of suppuration about the deep flexors of the forehead and hand. After first evacuating the pus, the hot air was applied for several hours every day. One man had reported seventeen such cases, and in sixteen there resulted perfect function of the arm and hand. The hot air treatment was of value in cases of tuberculosis. The "more blood" treatment, if applied by means of hot air, would, of course, greatly facilitate matters. It was a great satisfaction that Dr. Tyrnaner of Austria had succeeded in producing the necessary degrees of temperature by means of electricity. His apparatus, he thought, was very ingenious, was effective, and would soon be on the market in this country. His exhibit at the Post-Graduate Hospital deserved careful study.

Dr. D. Tyrnaner of Karlsbad demonstrated some of the apparatus for hyperemic treatment that he was using in the Karlsbad Institute Formerly, the local application of hot air was used with great disadvantage; the apparatus in use was heated by alcohol or gas lamps, and there were many other disadvantages. To produce heat by alcohol or gas lamps there was a great variation of the temperature in different parts of the apparatus, according to the distance of the part treated from the lamp. The temperature varied from 70° to 100° F. Near the lamp the patient might feel a burning heat, but on the opposite side the temperature was hardly raised. Again, all the lamps heated the room when the treatment was given nearly as much as the interior of the apparatus, and filled it with the products of burning alcohol and gas; this was very disagreeable. Another disadvantage was that it had been impossible to keep up the temperature for a long period in the interior of the apparatus at the same degree. At Karlsbad they had been applying local hot air treatment for many years in the treatment of various conditions, mostly cases of chronic gout, rheumatism, sciatica, and neuritis, as well as many cases of ankylosed joints. The inconvenience and discomfort of the older apparatus caused him to try the electric current for heating purposes. Dr. Kellogg of Battle Creek first used the electric light for heating purposes, constructing the electric light and baths now used all over the world. He had used electric lamps, but these fixed along the walls of a heating box did not raise the temperature to the degree which was necessary for the local application of hot air; electric lamps used as heaters did not raise the temperature higher than 150° to 180°, while for the treatment of certain conditions a temperature of 300° was needed. This temperature could be produced by the apparatus he had constructed, and was well tolerated by most patients. Dr. Tyrnaner showed some of the apparatus he had been using for many years with good results, and demonstrated the manner they worked. The apparatus was constructed of oak, with iron bars; outside they were covered with American fiber and inside with very hard, compressed asbestos; it could be thoroughly cleaned and disinfected when necessary. The heaters were deposited over the whole bottom of the apparatus, and they equally heated the entire interior. Each apparatus had from three to six heaters, which could be used all at the same time or singly. In this

way they had perfect control of the temperature. The apparatus could readily be adapted to street currents and in any house. The heaters were perfectly isolated, so that the patient could never touch them. Within eight to ten minutes the temperature could be raised to 220° or 300°. It was then easy to keep it up to the same degree or to lower it by turning off the switch. In his institute at Carlsbad, treatment was given simultaneously to six or more patients in the same room without raising the temperature of the room. This made it very agreeable for the patient, as well as for the physician, who should always be near the patient in order to watch him during the treatment.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of December 18, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	513	164
Diphtheria	401	39
Measles	509	16
Scarlet Fever	365	20
Smallpox	—	—
Varicella	117	—
Typhoid Fever	57	9
Whooping Cough	101	—
Cerebrospinal Meningitis	2	6
Malarial Fever	—	—
Totals	2,065	254

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 17, 1909:

Chickenpox, inoculation for, 366.
Child culture, intrauterine, 822.
Children, anatomical development regulating athletics, kindergarten school, and working, 664, 665; classification as a guide in determining segregation, 370; common disorders and diseases of, 451; degenerate, medical management of, 425; exceptional, 357, 370, 371; food intoxications in, 158; functional neuroses in, 694; urinary findings in, 919.
Chlamydozoa in nongonorrheal blenorrhea neonatorum, 830.
Chloride, excretion in infants, 704.
Chloroform, danger of, 446; for throat operations, 163; delayed poisoning treated with dextrose, 531; intravenous injections, 485; in phthisis, 449; Simpson and, 514; toxicity in relation to carbon tetrachloride, 366.
Chloroma, 916.
Cholecystectomy, for typhoid carriers, 578.
Cholecystitis, gangrenous, 861.
Cholecystostomy, 81.
Cholecystotomy, 586.
Cholera, agglutinins and bacteriolysins in, 608; hypotonic salt solution in, 1001; in Europe, 408; in Philippines, 528, 917; in Russia, 236; in Vladivostok, 654; laboratory infection, 960; new method of diagnosis, 614; nitrite poisoning? 1005; serumtherapy of, 1088; value of sanitary supervision in visitations, 1001.
Chorea, blood in, 484; following migraine, 116.
Christian Science, 189, 955; pragmatic view of, 73.
Circulation, peripheral, 493.
Clark, L. P., a note on the village treatment of nervous invalids, 435.
Clarke, A. B., diseases of the eye in pellagra, 1032.
Clarke, T. W., the rare forms of cyanosis, polycythemia, methemoglobinemia and sulph-hemoglobinemia, 143.
Cleftpalate operation, 747.
Climate, influence on metabolism, 471; Osler's errors, 999.
Club foot, care of in infancy without operation, 956; operative treatment, 541; treatment of paralytic, 742; treatment in infant, 791.
Coal miners, skin tuberculosis of, 618.
Coffey, R. C., gastric surgery of the present day, 95.
Cold, influence on bacteriemia, 503.
Colds, common, further researches into the bacteriology and vaccine therapy of, 920.
Colitis, appendicostomy for, 875; pneumococcus, 1039; surgical treatment, 31.
College of Physicians of Philadelphia, 866.
Colles' fracture, 240.
Colon, irritable states of, 198.
Color blindness, a method of temporarily removing, 366.
Colorado State Medical Association, 612.
Colostrum, biology of, 747.
Commissions for physicians, 371, 372.
Conjunctivitis, diphtheritic following measles, 691.
Connecticut State Medical Association, 824.
Constipation, chronic, 14, 201, 206, 366; mechanical, 576; spastic, 770.
Contagious diseases following San Francisco fire, 627.
Contract practice, 372, 373.
Copenhagen, letter from, 615.
Cornea, nodular opacities of, 577; opacities of, 958; regeneration of, 491.
Correspondence, Athens, 71; Berlin, 28, 112, 781, 1084; Canada, 742, 1084; Copenhagen, 615; London, 27, 70, 109, 155, 193, 238, 277, 319, 361, 413, 446, 488, 527, 573, 613, 656, 698, 739, 780, 825, 870, 915, 954, 1000, 1038, 1082; Paris, 194, 362, 741, 955, 1040; the Philippines, 156, 239, 528, 657, 917, 1001; Vienna, 110, 320, 489, 742.
Coxa valga rhachitica, 368.
Creosote of calcium, 205.
Cretinism, thyroid implantations in, 786; *x*-ray diagnosis of, 788.
Criminals, Borstal system for the treatment of juveniles, 651; sterilization of, 166, 863.
Crothers, T. D., the twelfth international antialcoholic congress held in London, 445.
Croup, histological alterations of the organs in, 380.
Crutcher, Howard, the sending of tuberculous patients from home, 26; consumption cures, 826.
Cuba, health department, 235; yellow fever prophylaxis in, 394.
Cumston, C. G., renal tuberculosis and its surgical treatment, 177.
Cyanosis during administration of nitrous oxide, 325; rare forms of, policythemia, methemoglobinemia, and sulph-hemoglobinemia, 143.
Cyst, of appendical remains, 619; chylous of iliac mesentery, 707; congenital of liver, 671; dentigerous, etiology and treatment, 538; hydatid of liver, 362; hydrated of spleen, 741; omental, 831; racemose ovarian, 104; twisted pedicle in parovarian, 439; of vagina, 119.
Cystocele, 957.
Cystoscopy in new growths of the urinary system, 743; in tuberculosis of kidney, 159.

D

Dale, J. E., brain tumor with unusual symptoms, 217; a urinary protein resembling Bence-Jones albumose, with clinical history and postmortem findings, 946.
Davidson, A. J., the importance of the early recognition of bone tuberculosis, 60.
Dayton, Hughes, percussion of the lungs, 148.
Deaf-mutes, can they swim? 910.
Deafness, hysterical, treated by suggestion, 703; preventable, 158.

Death, apparent, resuscitation by means of electric currents, 1009; second decennial revision of international classification of causes of, 877; sudden, 491, 530, 669; sudden from vocal cord paralysis, 920.
Deceit as a therapeutic measure, 191.
Deeks, W. E., and Shaw, W. F., the treatment of amebic dysentery, 806.
Defectives, children in New York, 526; education of, 23; problem of, 837.
Deformities, congenital, 543.
Delaware State Medical Society, 697.
Delivery, inertia after, 747; spontaneous postmortem, 959.
Dementia precox, value of thyroidectomy in catatonic form, 834.
Dentistry, *x*-ray in, 492.
Dermatitis exfoliativa, 624; of external auditory canal, 291; pediculoides ventricosus, 234, 966; satinwood, 441; *x*-ray, 790.
Dermatologist, the general practitioner as a, 187.
Diabetes, and gallstone surgery, 205; and pregnancy, 1088; and tuberculosis, 783; coma, 803; drug treatment, 205; geographical distribution, 831; in a child, 839,840; indications for forced labor in, 282; influence on eye operations, 549; oatmeal diet, 205; symposium on, 205; treatment as an infectious disease, 113, 205.
Diaphragm, adhesions of, 115; clonic spasm associated with cervical rib, 366; fatty degeneration in diphtheria, 104.
Diarrhea, chronic, 206; infantile, 364; surgical treatment, 431.
Diathesis, exudative, 782.
Diet and climate, 500; as a prophylactic and therapeutic agent, 247; for everyday use, 499; in chronic diseases, 290; symposium on, 206.
Digestion and odors, 745; sleep and, 73.
Digestive tract, modern surgery of, 833.
Digitalis, comparison of infusion and powder, 160.
Diller, T., a large glioma growing from the basal ganglia, producing symptoms suggestive of a growth in the frontal region, 345.
Diphtheria, antibacterial sera in treatment of, 671, 776; antitoxin, effect on the tuberculo-opsonic index, 115; antitoxin, therapeutic value expressed in units, 484; antitoxin, unusual symptoms due to, 568; ataxia following, 493, 524; cryptic, 532; effect of toxin and antitoxin on the heart, 190; latent, 573; metabolism in, 668; presence of sudanophile leucocytes in, 355; prognostic significance of blood pressure in, 960; pseudo due to pneumococcus, 366; pulmonary emphysema and fatty degeneration of the diaphragm in, 104; resistance of bacillus to drying, 756; septicemia, 151; streptococcus infection in, 1004; study of forty-one consecutive cases, 478; toxin and *x*-ray, 785; treated by massive doses of antitoxin, 819; treatment without medicine, 337.
Diplegia, cerebral, 1049.
Disease, transmission by fomites, 150.
Disinfection of skin with iodine, 271.
Dislocation of head of radius, 1046.
Dissections, preservation of, by a new method, 333.
Disseminate sclerosis, mutability of symptoms, 243.
Diverticulum, of appendix, 1005; Meckel's, 780; pharyngoesophageal, extirpation of, 1047.
Diverticulitis, sigmoid, 835.
Dobson, Lindley, a case of trichinosis, 606.
Doctors, are they derelict? 999.
Dorland, W. A. N., some practical aspects of the surgery of the peritoneum, 465.
Downing, B. C., blond idiots, 319; defective speech in backward and feeble-minded children, 729.
Drainage in abdominal and pelvic surgery, 710; in gynecology, 660; method of intestinal, 1005.
Dreams as a diagnostic and therapeutic aid, 458.
Duodenum, atresia of, 669; extirpation of, 198; perforating ulcer of, 332; ulcer of, 621, 751; ulcers, in marasmus 652; ulcer, surgery of, 753; ulcer, treatment of, 662.
Dysentery, amebic, 30, 529; amebic, in California, 168; amebic, surgical treatment, 810; amebic, treated by appendicostomy, 574; amebic, treatment of, 806; carriers, 737; preventive vaccination in, 960; tropical, 609.
Dysmenorrhea, cause of, 746; treatment of, 79.
Dyspepsia, a misnomer, 103; in malarial subjects, 336; intestinal, 399; of old age, 919.
Dyspnea following inhalation of menthol, 199.
Dystocia, caused by central fixation of uterus, 328; due to uterine ventrofixation, 785.
Dystrophy, pseudohypertrophic of upper and lower extremities, 1013.

E.

Ear, complications of exanthemata, 195; dermatitis of external canal 321; disease and nasal conditions, 658; disease of, and intestinal autointoxication, 703; nasal and pharyngeal conditions causing disease of, 583; reflex aural neuroses from eyestrain, 159; sepsis, 618.
Echinococcus cysts, 332; serodiagnosis of, 619.
Eccles, R. G., parisitism and natural selection, a medical supplement to Darwin's origin of species, 169; parasitism and natural selection, 757.
Eclampsia, 828; and leucocytosis of cerebrospinal fluid, 671; ovular theory of pathogensis of, 691; puerperal, diagnosis and treatment of, 974.
Economies of health, 784.
Ectopic pregnancy, operation for, 707.
Ectropion, 196.
Edema, angeoneurotic, with cirrhosis of liver, 324; pulmonary, in parturients, 504; pulmonary, physical therapy, 494; solid, lymphangioplasty for, 1005.
Education, leakage in our system, 370.
Edwards, R. F., the general death rate from malignant growths in the principal American cities, 1883 to 1907, 1030.
Efficiency, relation of posture to, 1086.
Einhorn, Max, a further contribution to our knowledge of intestinal dyspepsia, 399; a new method of catheterizing the pylorus and duodenum, 595, 621.
Electricity, high frequency, 150.
Electrolysis and bacteria, 194.
Elephantiasis, sporadic, 1004.
Ely, L. W., joint tuberculosis with special reference to its pathology (preliminary study of forty-five cases), 551.
Embolus, pulmonary and sudden death, 368.
Emotional expressions, organic basis of, 455.
Emphysema, in diphtheria, 104.
Empyema, 792; following pneumonia migrans, 325; race as a predisposing factor in, 668; treatment of fistulæ and abscess following, 334; with *B. coli*, treatment with antitoxin, 198.
Endarteritis, causing perforating ulcer of feet, 616.
Endocarditis, tuberculous, 336.
Endometritis, discussion of, 327.
Enema, high, 323.
Enteritis, diphtheritic, 711.
Entomological research, 527.
Entropion, 196.
Epidermolysis bullosa, elastic tissue in, 626.
Epididymitis, gonorrheal, operative treatment of, 944.
Epilepsy, calcium salts in, 365; cardiac, 72; etiology of, 959; in childhood, 315; in relation to menstrual periods, 744.
Epiphysitis, chronic of tibia, 541.
Epistaxis, treatment of, 280.
Epithelioma, cystic benign, 627; of lip, 82; morphea like, 240.
Erlanger, Joseph, the auriculoventricular bundle and Stanley Kent, 912.
Eruptions after abdominal operations, 274.
Erysipelas, etiology of, 746; and scarlatina, 503.
Erythema, preceding smallpox, 618; relapsing scarlatina from desquamative, 188.
Erythroderma squamosum, 624.
Esbach test, modification of, 191.
Esophagus, spasmodic stenosis of, 667, 995; surgery of, 539.
Ether, administration by means of nasal tubes, 365; relation of, to immunity, 80.
Ethyl chloride, as a general anesthetic for operations in the throat, 688.
Eustachian tube, in relation to mastoid operation, 1070; ventilation of, 280.
Evolution, role of visual function in, 421.
Exanthems, aural complications, 195; differential diagnosis, 75; new, 71.
Exercise, muscular, in restoration of function, 363.
Exophthalmic goiter, 632; ligation of upper poles of thyroid gland, 834; medical treatment of, 833; postoperative results of, 834; surgical treatment of 834; treated by *x*-ray and sour milk, 1043.
Exophthalmos in nephritis, 737.
Exostoses, multiple, with myositis ossificans, 540; osteogenic congenital, and tuberculous dystrophies, 355.
External auditory canal, superficial dermatitis of, 291.
Exudative diathesis, 566.
Eye, conjunctival ecchymosis in the newborn, 1076; danger of plated instruments in operations on, 159; diseases in pellagra, 958, 1032; horizontal oscillation in paralysis of the orbicular branch of the facial nerve, 457; influence of diabetes on operations, 549; prognosis of diseases of, 157; scissors magnet extraction of foreign bodies, 30; simple inspection of, as an aid in diagnosis, 530; vision in hysteria, 158.
Eye strain, with reflex aural neuroses, 150.

F.

Fallopian tube, hernia of, 734.
Fast, notes on a thirty days', 32.
Fauntleroy, P. C., some notes on the last epidemic of yellow fever in Cuba, 982.

Feces, bactericidal power of in nurslings, 600; chemical examination of, in infants after gastroenterostomy, 1002; proteolytic ferment in infants, 875.
Federal Bureau of Health, 1035.
Fee, 27.
Feeble minded, care of, 527; defective speech among, 729.
Feeding, artificial, 781; scientific, 586.
Feet, giant, 1043; weakened, 29.
Felderbaum, D., the diagnosis of tricuspid stenosis, the report of a case with tracings, 347; a wrist support for sphygmographic tracing, 819.
Ferments in stools, 199; and antiferments, new test for, 921.
Fernandez, F. M., nonspecific uses of antidiphtheritic serum, 774; a case of total ophthalmoplegia, 992.
Fetus, physiological osteiod in, 619.
Fibroma molluscum, a case of, 1090; multiple, 627.
Filariasis, radium treatment of, 358; nocturna, 282.
Fisher, J. W., a note on the staining of blood films, 564.
Flatfoot, plates, conservatism in the use of, 312; remarks on, 311; tendon transplantation in, 542.
Flies in Manila, 1001.
Fomites, in transmission of disease, 150, 361.
Fontaine, B. W., permanent blood pressure records, 607.
Food intoxications in children, 158.
Foodstuffs and alimentary functions, 206.
Football, 820; reformation of, 940.
Foundling Asylum, playground for, 1037.
Fowler, E. P., instruction in the hospital corps, 262.
Fowler position, 526.
Fracture, Colles, with lateral deformity, 240; of thigh in newborn, treatment of, 1044.
France, medical education in, 264.
Francine, A. P., and Landis, H. R. M., a case of idiopathic hydropneumothorax, with complete recovery, 856.
Frenzy, transitory, 402.
Freudenthal, Wolff, empyema of the antrum of Highmore, its relation to other diseases, and its treatment, 680.
Friedenwald, Julius, on the development of gastroenterology in America, 589, 621.
Frontal sinus, intranasal drainage of, 700.
Fulguration, biological action of, 786; in cancer, 195, 622, 951.
Fuller, Eugene, relief of urinary and genital conditions through surgery of the seminal vesicles, including a summary of the author's experience, 717.
Furunculosis, treatment of vaccines, 368.

G.

Gaines, L. M., the early diagnosis of pulmonary tuberculosis, 351.
Gall bladder, disease, gastric symptoms of, 599; perforation of, 861; surgery of, 750.
Gallstones, 29; in cystic duct, 861; disease, terminal events in, 711; latent, 751.
Gangrene, arteriovenous anastomosis for, 661, 701.
Gant, S. G., surgical treatment of diarrhea, 431.
Gardiner, J. P., the report of a peculiar case of meningitis, in which treatment by antimeningococcic serum was attempted, 62.
Gartner's bacillus infection, agglutination for typhoid in, 619.
Gasometer, clinical, 82.
Gastralgia, treatment of, 651
Gastroenterus, pathogeny of certain epidemics of, 756.
Gastroenterology, development in America, 589.
Gastroenterostomy, clinical results of, 598; feces of infants after, 1002; immediate results and surgical complication of, 622; physiological aspects of, 621,917.
General paresis, blood pressure in, 449; errors in diagnosis, 452; juvenile, 1013; remissions in, 195.
Germany, medical education in, 264; statistics of physicians in, 782.
Gibson, C. L., tuberculosis of the pericardium cured by incision and drainage, 216.
Glanders, chronic in man, 830; of upper respiratory tract, 830.
Glands, tuberculous mediastinal in children, 830.
Glaucoma, cyclodialysis in, 492; primary hemorrhagic, 415.
Glioma, growing from basal ganglia, 345.
Glottis, edema of, 840.
Glycosuria, experimental, 325; following typhoid fever, 74; relations of islands of Langerhans to, 621; in women, 1044.
Goiter (see exophthalmic goiter); excision under local anesthesia, 785; unusual case, 197.
Gonococcus, persistence in the prostate, 659; septicemia, treatment of, 194.
Gonorrhea of children, 619; genital canal block following, 837; ionization in, 956; means of checking contamination, 880; microscopic examination of prostatovesicular secretion in, 304; treatment of, 18, 98, 123; treatment, symposium on, 1051.
Gordon, Alfred, pathogenesis of tabetic arthropathies based upon an anatomoclinical study of two cases, 812.
Gould, G. M., the rôle of visual function in animal and human evolution, 421.
Gout, American, 1087; diminished pressor bases excreted, 365; excretion of chlorides in, 365; local sepsis, as a factor in, 1088.
Granuloma annulare, 628.
Great Britain, vital statistics, 22.
Greek medicine, Fitzpatrick lecture on, 1000.
Greeley, H., the great improvement in many advanced cases of pulmonary tuberculosis under sanatorium care, 648; the new law regulating the location of the tuberculosis sanatoria, 488;
Gunshot wound, of brain, 376; of thigh, 836.
Guntzer, J. H., scleroma of the upper respiratory tract, 120.
Gynecology, drainage in, 660; radium and *x*-ray in, 355; radium therapy in, 943.

H

Hagner, F. R., a supplemental report on the operative treatment of gonorrheal epididymitis, 944.
Hair, ball in stomach, 415; removal of, 74.
Hall, J. N., a clinical study of six hundred cases of heart disease, 816.
Halux valgus, etiology, 542.
Hands, hypertrophic osteoarthropathy of, 31.
Harrower, H. R., the estimation of the urinary ammonia and a new instrument for its rapid estimation, 354.
Harvard Dental School, 1110, department of public health at, 108
Harvey celebration, 825.
Harvey lectures, 910.
Hayden, J. R., the treatment of specific urethritis (gonorrhea) in the male, 68.
Hay fever, immunization treatment, 1041.
Head nodding, 366.
Health, rules of, 894; Federal bureau of, 1035.
Heart, acute overstrain of, 780; aortic systolic murmur, 139; auricular fibrillation, 1043; disease, baths, and exercise in treatment of, 502, disease, diagnosis of tricuspid stenoses, 347; disease, in infancy and childhood, 448; disease, intravenous use of strophanthin in, 783; disease, nature of unilateral pleuritic effusions in, 568, 521; disease, study of six hundred cases, 816; early signs of rheumatism of, 493; effect of digitalis on ventricular rate, 841; effect of diphtheria toxine and antitoxine on, 190, extrasystolic arrhythmia, 756; failure cells in the urine, 694; histology of hypertrophied muscle, 619; influence of baths on size, 75; influence of sinusoidal baths upon, 921; interesting specimen of, 82; murmurs, aremic, 529; new sign for nervous, 742; origin of presystolic murmur, 781; source of power, 782; thromboses of, 828; temperature of, 320; treatment of chronic degenerative lesions of, 197.
Hebosteotomy and extraperitoneal cesarian section, 1044.
Hebotomy, value of different methods, 263.
Heels, painful, 282.
Hellman, A. M., a case of Mongolian idiocy, 772.
Hematoma of abdominal wall simulating dermoid tumor, 1010.
Hematometra in an aged woman, 1010.
Hematopoiesis, relation to purpura, 366.
Hematuria, congenital, hereditary, and family, 416.
Hemiplegia, from cerebral arteritis in heredosyphilitics, 463; infantile cerebral, 542; organic following shock, 160; transient with migraine, 75.
Hemochromogen, method of obtaining crystals, 661.
Hemoglobinuria paroxysmal, hemolysis in, 243.
Hemolysis, in cancer, 829; diagnostic significance in cancer and tuberculosis, 901.
Hemophilia, 537; blood transfusion in 1046.
Hemorrhage, calcium lactate in, 505, cerebral of infancy, with operation, 666; intraperitoneal in wounds of intestines, 100; intestinal, etiology and treatment, 182; tuberculous, 323, 407.
Hemorrhagic conditions, review of recent experimental work on, 956.
Hemostatic, atropine as, 905
Hernia, of Fallopian tube, 734; inguinal containing appendix, 321
Herpes of defeat, 151.
Herpes zoster oticus, 458
Herrick, A. B., the surgical treatment of very severe and late cases of amebic dysentery, 810
Hicks, John R., the ophthalmotuberculin reaction, 217

High frequency currents, 481, 615; in treatment of malignant tumors, 368; use and abuse of, 234.
Hip, etiology of congenital dislocation of, 577; fracture of, 782; operation for congenital dislocation, 661; toxic arthritis of, 909.
Hirschberg's febrile infection, 745.
Hirschprung's disease, 494.
Hoff, J. Van R., is there a venereal peril for us? 896.
Holmes memorial meeting, 655.
Hookworm (see uncinariasis), 608.
Hordeolum, recurrent, 576.
Horse serum, idiosyncrasy to, 569.
Hospital, the first American, 562; corps, instruction in, 262, 289.
Houghton, H. A., the differential diagnosis between certain forms of tertial malaria and enterogenic intoxication, 768.
House fly, campaign against, 21; typhoid epidemic due to, 68.
Huron Street Hospital, 154.
Hydatid cysts, reaction for, 195.
Hydrocele, operation for, 81.
Hydrocephalus, treatment of, 777.
Hydrochloric acid secretion, influence of hydrogen peroxide on, 872.
Hydropneumothorax, idiopathic, with complete recovery, 856.
Hygiene, age problem of industrial, 881; instruction in medical college, 879; school instruction in, 879; sex problem in industrial, 881.
Hyperemic treatment of Bier in surgery, 1091.
Hypertension in nephritis, 35, 1003.
Hypnoidal state and method of hynoidization, 250.
Hypnotic suggestion therapeutic, value of, 204.
Hypnotism, blister produced by, 831.
Hypodermic medication in modern therapy, 290.
Hypophysis cerebri, 240; extract of, 320; teratoma of, 617; tumor of, 32,
Hypospadias, difficulties in operation, 121, 363.
Hysteria, Babinski's theory and traumatic neuroses, 557; pseudoparalysis agitans, 160; reflexes in, 456; traumatic, 268; visual fields in, 159.
Hysterical deafness treated by suggestion, 703.
Hystero-organic disease, 190

I.

Ichthyosis and the thyroid body, 859.
Idaho State Medical Association, 276.
Idiocy, amaurotic family, 839; Mongolian, 280, 454, 772.
Idiosyncrasy to horse serum, 569.
Ileus, biliary, 313; postoperative duodenal, 921.
Immunity, critical remarks on Ehrlich's side chain theory, 673.
India conference on malaria, 780.
Indian army, health of, 614.
Indicanuria, 829; practical test for, 702.
Indigestion, 775; surgical treatment, 83.
Infants, antiproteolytic substances in blood, 785; bactericidal power of feces in nurslings, 600; care of, 781; morning's milk for, 116; mortality, conference on prevention of, 865; mortality in Brooklyn, 245; mortality, influence of diet on, 1041; mortality, relation of tuberculosis to, 1002; pancreatic cyst in, 84; prophylaxis in, 113; summer death rate for, 494.
Infant feeding, 66, 167, 576; biology as a basis of, 962, 1002; caloric method of, 105; combined method of, 745; during illness, 963; milk sugar in, 105; percentage principal in, 963; rôle of albumen in, 747; serological studies of, 960; Soy beans in, 670.
Infarct, hemorrhagic renal, 482.
Infections, a new diagnostic skin reaction for acute, 576.
Inflammation, anesthesia in control of, 472.
Influenza, aortitis, 1013; a bacillus the cause of an epidemic of bronchopneumonia, 1088; carriers, 667; cultures as a means of diagnosis, 667; in hospital infection, 667; pneumococcus infection simulating, 994; with marked cerebral symptoms, 1004.
Inoculation of staphylococcus, 449.
Insane, after care of, 517; criminal 358; early treatment of, 405.
Insanity, alcoholism as a causative factor in, 906; borderland cases of, 1078; fresh air in treatment, 499; traumatic, 660.
Instruments, danger of plated, 159.
Insular sclerosis, inflammatory nature of, 863.
Insurance examiner, practical suggestions for, 616.
Intermittent claudication, 1006.
International antialcoholic congress in London, 445; dental congress, 443.
Intestines, anastomosis of, 332; autointoxication and ear disease, 703; diagnosis of tuberculosis of, 195; dyspepsia of, 399; etiology and treatment of hemorrhage, 182; infective processes of, 870; irritating effects of cathartic drugs, 670; large, surgery of, 375; method of drainage, 1005; obstruction of, 618; obstruction, cause of death, 81; osmotic power of, 320; resection of, 330; wounds of, 199.
Intestinal, antisepsis and peptic digestion, 829; intoxication diagnosed from tertian malaria, 768; stasis, chronic, 201.
Intussusception, cecocolic, caused by primary invagination of the appendix, 1047; due to unusual cause, 840.
Iodine for disinfection of the skin, 271.
Iritis, unusually intractable case, 349.
Ivy poisoning, 232.

J.

Jackson, J. N., cancer of the female breast, 940.
Jackson, T. W., the clinical side of discases in the Philippine Islands, 511.
Jaundice, operative treatment of, 329; persistent in child, 791.
Jaw, undeveloped lower, 196.
Jervey, J. W., the significance of certain pathological conditions of the fossæ of Rosenmüller, 468.
Jewett, Charles, skin disinfection with iodine in abdominal and other operations, 271.
Joints, fate of damaged, 281; infections, etiology and pathology of, 80; place of arthrotomy in tuberculous disease, 540; sacroiliac, 745; surgery, animal membrane in, 485, 542; tuberculosis of, 448, 551; tuberculosis of, treatment, 330.
Judson, A. B., the hygiene of the air passages, 270.
Juvenile Court of Chicago, 665.

K.

Kakels, W. S., early trephining for severe injuries of the skull, with a report of cases operated upon, 934.
Kala-azar in Sicily, 662.
Karo, Wilhelm, tuberculin for the diagnosis and therapy of renal tuberculosis, 554.
Keen, J. R., military obligations of the medical profession, 253.
Kentucky State Medical Association, 779.
Keratitis, interstitial, 114; interstitial in acquired syphilis, 690; nodular, 872; parenchymatous in acquired syphilis, 186.
Kidneys, calculi of, 794, 795; hemorrhagic infarct, 482; permeability to bacteria, 661; prognosis and treatment of tuberculosis of, 872; sarcoma of, 793; surgery of, 177; transplantation of, 116; tuberculosis of, 159, 177, 554.
King, H. M., the tuberculo-opsonic index in the relation to the temperature curve in active tuberculosis and its value in diagnosis in suspected or arrested cases, 1; on the construction of an efficient and economic diet in tuberculosis, 633.
King, R. W., a simple method of preparing a useful stain, 103; the preparation of Romanowsky stains, 733.
Knees, relaxed in children, 827.
Knopf, S. A., life insurance in its relation to the prevention of tuberculosis, 297; the anti-tuberculosis war and the Red Cross Christmas stamps, 998.

L.

Labor, complicated by nervous overdevelopment, care of, 1011; forced in diabetes, 282; indications for induction of, 164, 165; longitudinal hypertrophy of the cervix in, 1033; missed, treated by abdominal section, 324.
Laboratory work by the country physician, 615.
Lactic acid, and lactic acid bacilli, 926; bacilli, in chronic suffuration of the nose, 195; bacilli, new method of applying in suppurating wounds. 991.
Lake Michigan water, 660.
Lamb, Captain Henry, memorial to, 108.
Laparotomy, pulmonary complications of, 323.
Larynx, cancer of, 580, 641, 700; cancer of, treatment, 118; cancer, early diagnosis of, 641; excision of, 333; stenosis of, 414; stenosis of, cured by intubation, 1069; tuberculosis of, 323; tumor of, 118.
Landis, H. R. M., and Francine, A. P., a case of idiopathic hydropneumothorax, with complete recovery, 856.
Leadless glaze exhibition, 1039.
Lead poisoning, 699; pathology of, 703.
Le Boutillier, W. G., the national guard surgeon, 259.
Lecithin, action of in anesthesia, 441; and nervous exhaustion, 478.
Le Conte, J. N., spastic constipation, a symptom, 770.
Lectures, scope and value of, 878.
Leg, treatment of chronic ulcer of, 959.
Lepra maculosa, a case of, 1091.
Leprosy, 45; bacteriology and pathological anatomy, 483; cultivation of bacilli, 237; nasal secretions in diagnosis, 865; treatment by chaulmoogra oil, 239.
Leptothrix meningitis, 252.
Leucocytes, sudanophile in diphtheria, 355.
Leukemia, effects of *x*-ray in infantile, 1033; etiology of, 692; pathology of, 529.

Levulosuria and hepatic cirrhosis, 38; with tumor of liver, 199.
Lewis, J. P., malformations of the nasal septum, 309.
Libraries, directory of, 533.
Life insurance, and public hygiene, 881; and prevention of tuberculosis, 297; and preventive medicine, 272.
Light, incandescent and arc in medicine, 1028; pigmentation, and new growth, 450.
Lightning stroke, psychoses following, 358.
Lip, epithelioma of, 82.
Liquor, problem, 436; traffic, the drug store and, 610.
Lisping, 793.
Liver, affections in children, 916; angioma of, 927; cirrhosis, frequency in nonalcoholics, 1075; cirrhosis, operative treatment, 37; cirrhosis, value of alimentary levulosuria in diagnosis of, 38; cirrhosis, with angioneurotic edema, 324; congenital cysts of, 671; fatty, infiltration in infant, 575; hydatid cyst of, 362; malignant adenoma of, 662; metabolism of the extirpation of, 489; pathogenesis of cirrhosis, 243; tumor of, with levulosuria, 199; umbilical hemorrhage in cirrhosis, 494.
Lochia, bacterial examination of normal, 1060.
London, letters from, 27, 70, 109, 155, 193, 238, 277, 319, 361, 413, 446, 488, 527, 573, 613, 656, 698, 739, 780, 825, 870, 915, 954, 1000, 1038, 1082; University, 825; women hotel visitors in, 573.
Lordosis and albuminuria, 578, 691.
Loveland, B. C., traumatic hysteria in its relation to surgery, 268.
Ludlum, S. D. W., and White, E. C., studies with the Wassermann reaction, 1073.
Ludwig's angina with facial carbuncle and parotites, 242.
Lungs, complication following laparotomy, 323; embolus of, 368; influence of athletics on capacity of, 1088; percussion of, 148; physical therapy for edema, 494; puncture, a new application of clinical pathology, 919; secondary carcinoma of, 145; temperature of, 320; treatment of bullet wounds, 578.
Lupus erythematosus, 242, 700.
Lymphangioma xanthilasmoidium, 624.
Lymphangioplasty for solid edema, 1005.
Lymphatic obstruction, treated by radium, 282.
Lymphatics of upper limb, 830.
Lymphocytes, origin of, 580.

M.

McCosh, memorial to Dr. Andrew, 69, 997.
McCreery, F. R., report of a case of hemorrhagic renal infarct, 482.
McConkey, T. G., is lobar pneumonia inflammation of the lungs, 727.
McKinniss, C. R., a statistical study of alcoholism as a causative factor in insanity, 906.
McLaughlin, J. W., critical remarks on Ehrlich's sidechain theory of immunity, 673.
McLaughlin, W. B., a new method of applying lactic acid bacilli in the treatment of suppurating wounds, 991.
Macht, D. I., mumps vs. tetanus, a clinical note, 218.
Magnesium and calcium, physiology and pathology of, 1006; sulphate, anesthesia, 1042; sulphate, in tetanus, 43; intoxication with, 408.
Makuen, G. Hudson, a brief history of the treatment of stammering wtih some suggestions as to modern methods, 1015.
Malaria, algid, 38; analogies to syphilis, 112; complications of, 113; congenital, 669; diagnosed from intestinal intoxication, 768; dyspepsia in, 336; Indian conference on, 780, 870; latent diagnosis of, 532; prevention of, 735; sanitation in Isthmas, 56; treated with injections of quinine, 577.
Malignant growths, death rate in American cities, 1030.
Malpractice, a celebrated suit, 372.
Mandible, simple method of treating fractures of, 661.
Mania, febrile, 1613.
Manila, sewage system in, 658.
Marasmus, duodenal ulcers in, 652.
Marmorek's serum used locally, 532.
Marshall, V. F., cesarean section in placenta previa with report of a case, 601.
Mastoid, relation of eustachian tube to radical operation, 1070; *x*-ray of, 617.
Mastoiditis, complicated by purulent leptomeningitis, epidural abscess and sinus thrombosis, 650; indications for operation, 72.
Maternity hospitals in Germany, 781.
Matson, R. C., serology of syphilis, 337.
Maxilla, sinusitis and osteitis of, 882.
Measles, decreased tuberculin sensitiveness to, during, 532; diphtheritic conjunctivitis following, 691; early diagnosis of, 188, 821; treatment of, 795; German, lymphadenitis in, 1006.
Meat poisoning, 23.
Meconium, formed, simulating intestine, 669.
Medical, education, 285, 370, 833; education in France and Germany, 264; education, our system, 474; education, plea for reform in, 855; expert testimony, 166; practice act in Washington State, 525; science, element of rationality in, 496; students in London, 826; versus legal responsibility, 576.
Medical Society of the Missouri Valley, 587.
Medical Society of New Jersey, 163.
Medicine, the widening sphere of, 157; tropical, 919.
Meisenbach, R. O., conservatism in the use of flatfoot plates, 312.
Meltzer, S. J., the auricuto-ventricular bundle and Stanley Kent, 914.
Meningitis, cerebrospinal, bacteriological diagnosis of, 587; cerebrospinal, in the nursling, 1006; cerebrospinal, mode of infection, 66; cerebrospinal, prevention of, 484; cerebrospinal, treatment, 62, 198, 530, 828; leptothrix, 252; posterior basic, 314; subacute as a complication of respiratory troubles in children, 632.
Meningococcemia, 741.
Menstruation, vicarious in the form of lip hemorrhage, 831.
Mental diseases, blood test for, 106, 234, 235, 367; disorders of women, 650.
Menthol oil, dyspnea following nasal inhalation, 199.
Meralgia paraesthetica, 625.
Mercury, intravenous injections of, 828; and sulphur, 321.
Metabolism, influence of meteorological and climatic conditions on, 471.
Methemoglobinemia, 143.
Metropolitan Life Insurance Co., 868.
Meyer, Emil, stenosis of the larynx, cured by intubation, 1069.
Michigan State Medical Society, 525.
Micromotoscope, 1060.
Midwives, act in England, 527; regulation of, 272.
Migraine, analogy to rheumatism, 364; following chronic chorea, 116; hemiplegia with, 75.
Military obligations of the medical profession, 253, 289.
Militia, field work, 1004.
Milk, middle mixtures, 364, mother's, preserved, 320; pasteurization of, 962; physiology of secretion, 368; pure, 742, 964; sugar in infant feeding, 105; super-nutritive properties of, 168; supply, co-operative efforts in supervision and control, 880; Wassermann reaction in, 1044.
Mind, influence over body, 954.
Minnesota State Medical Association, 779.
Mistakes in diagnosis, 919.
Mitral stenosis, crescendo murmur in, 493.
Molluscum contagiosum, 449.
Moral prophylaxis, 1061.
Moro reaction, 199.
Morphinism, treatment by scopolamine-dionine, 490.
Morrow, P. A., results achieved by the movement for sanitary and moral prophylaxis, outlook for the future, 1061.
Mortality of American cities, 910.
Morton commemoration exercises, 695.
Moschcowitz, A. V., the technique of amputation with especial reference to the osteophathic methods, 1017.
Mosquitoes, 239; in New Jersey, 360; a possible natural enemy of, 531, 574.
Mouth, sepsis of, in connection with throat diseases, 114.
Moving pictures of microscopic objects, 869.
Much-Holzmann reaction, 106, 234, 235, 367.
Mucous colitis, pain in, 198.
Mulot, O. L., our medical educational system, 474.
Mumps vs. tetanus, 218.
Murmur, diastolic in dilatation of aorta, 160.
Myomectomy, abdominal, 445.
Myositis, chronic rheumatic, 323; ossificans, associated with multiple exostoses, 540.
Myxodema, juvenile, 660; thyroid implantation in, 786.

N.

Nascher, I. L., the treatment of diseases of senility, 987.
Nasopharynx, importance of thorough examination in ear disease, 584; in infants and children, 582; new mode of access to, 615.
National Association of Military Surgeons, 655.
National Association of Railway Surgeons, 655.
National guard surgeon, 259, 289; health administration, 879.
Navy, annual report of the Surgeon-General of the, 1077; medical department of, 256, 289.
Negroes, antituberculous work among, 273, 569; physicians, 607.
Nelson Morris Memorial Institute for Medical Research, 499.
Nephritis, blood pressure in, 366; exophthalmos in, 737; experimental, clinical value, 34; hypertension in, 35, 1003, and inflammation of parenchymatous organs, 1044; salt-free diet in, 35, 1003; with edema of glottis in a child, 840.

Nerve anastomosis, 575; force and deep reflexes, 452.
Nervous diseases, pathology of, 700; exhaustion, and lecithin, 478; invalids, village treatment of, 435; operative treatment of epileptiform trifacial, 1083; trifacial, 1087.
Neuralgia alcohol injections, 872; treatment by deep injections, 837; trigeminal operation for, 111.
Neurasthenia, 662, 924.
Neuritis, multiple and alcohol, 746; occupation, 457; syphilitic, 1013.
Neurological institute, 910, 911.
Neuron theory, present position of in relation to neuropathology, 959.
Neuroses functional in children, 694; occupation, 196; reflex to nasal abnormality, 837; traumatic, 557.
Neustaedter, M., a contribution to the study of tremors, 91.
New born, conjunctival ecchymosis in, 1076; osteomyelitis in, 188.
New Brunswick Medical Association, 237.
New Jersey, mosquitos in, 360.
New York Academy of Medicine, presentation of bust of Dr. Bull, 118.
New York, antituberculosis campaign in, 653.
Nichols, J. B., the influence of meteorological and climatic conditions on metabolism, 471.

Pityriasis rosea, with [illegible] 917
Placenta, as a culture medium for microbes, 1013; fixation of bile pigments in, 144; previa, 828; previa, cesarian section in, 681; previa, indications for electrotherapy and cesarian section, 916.
Plague, eradication from San Francisco, 903; inoculation against,

1070; rats and fleas, 657, in West Africa, 489.
Plaster of Paris, improvements in technique, 541.
Pleural effusions, in heart disease, 508, 521; percussion in, 199.
Pleurectomy, visceral, 334.
Pneumectomy, 1087.
Pneumococcic, arthritis, 196; infection, 668; infection, simulating influenza, 994; invasion of throat, 115, 366, 875, 916; invasion of the throat with pulmonary and laryngeal tuberculosis, 115.
Pneumonia, abdominal symptoms in, 417; camphor in, 610; in Colorado, 501; drug treatment of, 501; intravenous administration of strophanthin, 500; is it an inflammation of the lungs, 727; migrans involving entire lungs and empyema, 325; strophanthin in, 414; treatment of, 501; treatment by vaccines, 115, 917; treatment in infancy and childhood, 744; two rapidly fatal cases, 1043; typical and fractional, 959; venisection in, 501.
Penumonoconiosis, intestinal, 199.
Pneumothorax intreatment of pulmonary tuberculosis, 615.
Poisoning, anise water, 606; bismuth subnitrate, 74; delayed chloroform, 531; lead, 699, 703; meat, 23; quinine, 159, 1036, tobacco in an infant, 160.
Poliomyelitis, elecetricity in diagnosis and treatment, 566; etiology of, 875; extensive paralysis due to, 1049; of the foot, 566; in Massachusetts, 240; infectious nature of, 993; in Minnesota, 275; in New York, 409; in St. Paul, 360, 654; microorganism, 777; syphilitic, 456; Westphalian epidemic, 875.
Polycythemia, 143, 529.
Polyneuritis syphilitica, 747.
Polyserositis, 450.
Pons Varolii, hemorrhage into, 31.
Porter, R. H., the medical management of degenerate children, 425.
Posey, W. C., report of an unusually intractable case of iritis, with some remarks on the etiology of iritis, 349.
Postgraduate study, 613.
Posture, relation to human efficiency, 543, 1086.
Pottinger, F. M., further observations upon rigidity of the chest muscles as a sign of involvement of the pulmonary parenchyma, 685; a new physical sign, probably a skin reflex, whereby solid organs, such as the heart and liver and inflammatory processes found in the lungs and pleura may be detected by palpation, 691.
Precancerous state, 316.
Pregnancy, amaurosis during, 921; and diabetes, 1088; complicated by nervous overdevelopment, care of, 1011; gastric secretion during, 106; interstitial, 1040; ovarian at term, 709; treatment of uterine cancer during, 289; tubal, conditions simulating, 79; tuberculosis and, 243, 439, 615, 1086; vomiting of, 786; vomiting of, treated by suprarenal opotherapy, 439.
Pre-Rolandic area, sensory functions of, 452.
Press, scope and value of, 881.
Prevention and cure, 616.
Prophylaxis, sanitary and moral, 1061
Prostate, calculus of, 794; enucleation of, 332; persistence of gonococcus in, 659; sarcoma of, 836; treatment of, 291; x-ray examination of, 116.
Prostatectomy, stenosis of vesical outlet following, 565; sequels of perineal, 334; suprapubic, 374.
Prostatitis, acute gonorrheal, 985.
Prostatovesicular secretion, examination of, in gonorrhea, 304.
Prostitutes, necessity of isolation to prevent propagation of syphilis, 879.
Preventorium at Lakewood, 949, 952.
Proteolytic ferment in infant's feces, 875.
Protozoal diseases in tropics, 573.
Pruritis, and treatment of, 530; senile, 613.
Pseudodiptheria, due to pneumococcus, 366.
Pseudoopotherapy, true versus, 206.
Pseudoparalysis, agitans (hysterical), 160; syphilitic, 577; psoriosis, etiology of, 625; parasitism of, 625.
Psoriasis, nature of, 1079
Psychasthenia, 322.
Psychology, some new fields and methods in, 918.
Psychoneuroses, 659; Freud's conception of, 1065.
Psychoreaction, 106, 234, 235, 367.
Psychoses, antitrypsin in blood of, 1005; delayed traumatic, 195; following lightning stroke, 358.
Psychotherapy, symposium on, 248.
Public Health Education Committee, 192.
Public hygiene, and life insurance, 881; in betterment of home life, 880; in prevention of dependency, 880.
Puerperal, eclampsia, preventive treatment, 494; pyemia, surgical treatment of, 1088.
Puerperium, a plea for a rational, 366; tarsalgia in, 503.
Purge, pre-operative, 710.
Purpura, hæmorrhagica with abdominal crises, 282; Henoch's, 155; relation to hematopoiesis, 368.
Pyemia, puerperal, surgical treatment of, 1088.
Pyloric stenosis, infantile. (See pylorospasm.)
Pylorospasm, 238, 873; cured without operation, 838, 874; etiology of, 356; rectal injections of saline in, 822.
Pylorus, cancer of, 624; foreign body associated with cancer of, 624; new method of catheterizing, 595.
Pyonephrosis, 795.
Pyorrhea alveolaris, opsonic treatment of, 827.

Q

Quinine, dermatitis, 159; fatal poisoning by, 1036.

R

Rabies, 616; danger-free method of using virus, 701.
Rachitis, blood in, 442.
Radioactive charcoal, 416.
Radioactivity and cancer, 70, 233, 242.
Radiography in tuberculosis of kidney, 159.
Radium, desensitizing the skin to, 152; influence on metabolism, 198; influence on uric acid salts, 75; in gynecology, 355, 943; Institute of America, 868; in treatment of cancer, 487, 958; treatment of filariasis, 282, 358.
Radius, dislocation of the head, 1046.
Rags, infection through, 238.
Reasoning faculties, disguised starvation and the, 1086.

Stark, H. S., diabetic coma, is it due to acidosis? 803.
Starvation, disguised, and the reasoning faculties, 1086.
State Board examination questions and answers, California, 293; Colorado, 1054; Georgia, 39; Illinois, 544, Mississippi, 377; New Jersey, 458, New York, 207; North Carolina, 882; Ohio, 712; Oregon, 966; Vermont, 628; Virginia, 795; West Virginia, 124.
State hygienic laboratory at Ithaca, 696.
Status lymphaticus, 791; death following tonsilectomy, 583.
Sterility, a common cause of, treatment, 1040; treatment of, 79.
Sterlization, of criminals and defectives by vasectomy, 166; of skin, 417; of tuberculous pregnant women, 160.
Still birth, rigor mortis in, 325
Still's disease, 780.
Stokes, C. F., some features of the medical department of the navy in peace and in war, 256.
Stokes Adams syndrome, treatment of, 292.
Stomach, ectasia and insufficient pylaris, 322; acute dilatation, 838, acute dilatation, post-operative, 743, cancer of, diagnosed by x ray, 115; cancer of, 622, 783; capacity and tone of, 490; examination of contents, 1087; free hydrochloric acid in, 72; hair ball in, 415; illumination of, 327; removal of foreign bodies from, 958; relation to pelvic disease, 159; surgery of, 95, 490; surgery of in America, 589; ulcer of, 585, ulcer, diagnosis

of, 754; ulcer, diagnosed by bismuth, 407; ulcer, etiology and pathology of, 574; ulcer, etiology and symptomatology of, 752; ulcer, surgery of, 753; ulcer, treatment of, 116; ulcer in the young, 754, 827; value of test meal in diagnosis, 491; zymosia and the tuberculosis problem, 322.
Stomatitis, ulcerative, 232; unusual type in infant, 493.
Stools, of new born and their significance, 670; proteolytic ferments in, 199.
Stow, Bond, evidence controverting Rosenberger's tuberculous bacteremia hypothesis, 990.
Streptococcus, infection in diphtheria, 1004.
Stricture, of urethra, 836; diagnosis and treatment of, 587.
Stridor, congenital, 791.
Strophanthin, a clinical study of, 83; intravenous administration of, 414, 783; in pneumonia, 500.
Strophanthus, use in pediatrics, 355.
Strunsky, Max, remarks on flat foot, 311.
Strychnine, suprarenal extract and, 1080.
Styloid process, prolonged, 538.
Suicides, seasonal influence on, 499.
Sulph-hemoglobinemia, 143.
Sulphur and mercury, 321.
Summer diarrhea, predisposing causes and prevention, 245; hygienic and dietetic treatment, 246.
Sun baths, dangers of, 523.
Suprarenal, extract and strychnine, 1080; extract for vomiting of pregnancy, 439; insufficiency in scarlatina, 482.
Surface signs in diagnosis of deep-seated disease, 577.
Surgeon with inadequate preparation, 707.
Surgeon General of the Army, annual report of, 1034.
Surgery, Bier's hyperemic treatment in, 1091; comparison of aseptic and antiseptic methods, 1043; elements of success in, 750; of thorax, 334; tuberculous toxemia in, 749.
Surgical diseases, conditions simulating, 750.
Sweating, local, 197.
Swinburne, G. K., the therapeutic value of the antigonococcic serum and gonococcic bacterins, 687.
Symptom complex, new 23.
Synthesis, effect of modern, 291.
Syphilis, acquired, parenchymatous keratitis in, 186; analogies to malaria, 112; hemeplegia in hereditary, 463; inheritance of, 704; intensive treatment by Aachen method, 578; interstitial keratitis in acquired, 690; intramuscular mercurial injections, 164, 872; means of checking contamination, 880; new method of treatment, 786; police supervision and, 116; polyneuritis, 747; precipitin test for, 873; percocious tertiary, 645; provocative action of mercury, 199; pseudoparalysis, 577; reinfection in, 315; reinfection after nine years, 746; remarks on immunity, 746; serology of, 337, 873; tertiary, terminating in sudden death from abductor paralysis of the vocal cords, 920; transmission by vaccine, 879; treatment, 18; ultramicroscope in early diagnosis of, 577.
Syringomyelia, involving face, scalp, and larynx, 1013; monoplegic, 532; pharyngeal and laryngeal symptoms of, 532.

T.

Tabes dorsalis, Charcot's joint of hip, 1013; diagnosis of from general paresis, 457; early diagnosis of, 406; infantile in a girl of ten, 199; optic atrophy in, 240; origin of, 617; pain in, 457; pathogenesis of arthropathies, 457, 812; treatment, 659, 747, 828.
Tachycardia, inherited, 115; paroxysmal, disappearing after herpes zoster, 746.
Tactile memory, loss of, 111.
Talipes valgus, treatment, 542.
Tarsalgia, in puerperal state, 503.
Teeth, vitality of enamel, 241.
Tendons, anchoring transplanted, 542; transplantation, 782.
Teratoma, hypophyseal, 617; of soft palate, 582.
Testicle, undescended, malignant tumor of, 711.
Test meal, value in gastric diagnosis, 491.
Tetanus, 401; fecal origin of some forms of post-operative, 202; magnesium sulphate in, 43; mortality, 236; post-operative, 79; prognosis, 417; treatment of, 375; treated with serum, 616; versus mumps, 218.
Tetany, 110; action of glandular extracts after parathyroidectomy, 415; relapsing, 464.
Thaw decision, 316.
Thermotherapy, apparatus for, 111.
Therapeutic knowledge, has it kept pace with the advance of medical science, 023.
Thigh, gunshot wounds of, 836.
Thiocyanates, the natural physiological solvents of the body, 784.
Thomas, W S., are doctors derelict? 999.
Thomson, W. H., a severe case of scarlatina and of diphtheria successfully treated without medicine, 343.
Thorax, surgery of, 334.
Throat, chloroform anesthesia for operations on, 163; sore, 324.
Thrombosis, cardiac, 828; cavernous sinus, 582; median spinal artery, 456.
Thymus, and ovaries, 734; death, 491; death, an account of seven cases in one family, 669.
Thyroid, and ichthyosis, 859; implantations in myxedema and cretinism, 786; extract, in experimental tuberculosis, 160; extract, pharmacology of, 575; nevroarthritism, 1040.
Thyroidectomy, and a theory of cancer causation, 784; in treatment of catatonic dementia precox, 834.
Tic douloureux, 456; treatment of, 327.
Tobacco poisoning in an infant, 160.
Tongue, cancer of, 538; hemiatrophy of, 916; paralysis of after angina, 274.
Tonsils, 449; and teeth, 30; embryology of epithelium of crypts, 580; of infant, child, and adult, 580; hypertrophy of, in relation to tuberculosis, 104; opsonic index, and immunity, 520; tuberculosis infection through, 322.
Tonsillectomy, 10, 29, 539, 951; death from status lymphaticus following, 583; for rheumatism, 865; present status of, 975.
Tonsillitis, paralysis of tongue following, 274.
Toronto, General Hospital, 742; water supply of, 743.
Torticollis, etiology of, 450.
Tovey, D. W., the acetone treatment of inoperable carcinoma, 765.
Townsend, T. M., and Valentine, F. C., acute gonorrheal prostatitis, 985.
Trachea, primary cancer of, 581.
Trachoma, bodies, 704, 830; etiology, 160; hospital for, 108.
Transfusion, direct, of blood, 872; with note on hemolysis, 333.
Transplantation of kidneys, 116.
Transthermia, 700.
Traumatic neurosis, 196.
Tremors, a contribution to the study of, 91.
Trichinosis, a case of, 606.
Tricuspid stenosis, diagnosis of, 347.
Tristate Medical Association, 997.
Tropical medicine, 919; an American school of, 184; future of, 194.
Tropics, nations and, 870; protozoal diseases in, 573; ventilation in, 523.
True versus pseudoopotherapy, 206.
Trypanosomiasis, cerebrospinal fluid in, 1005.
Trypsin, determination of, 1087; treatment of cancer, 85, 219.
Tubercle bacilli, estimation of, 199; in the blood, 490, 662, 785, 818, 990; in the urine, 364; not demonstrated by the Ziehl method, 282.
Tuberculin, antibodies during specific treatment, 619; cutaneous reaction, 497; decreased sensitiveness to during measles, 532;; in progressive paralysis, 871; in renal tuberculosis, 554; on the nasal mucosa, 105; reaction, 217; test in orthopedics, 625; vaseline for conjunctival reaction, 1006.
Tuberculosis, 26, 285, 703; among orientals, 984; anaphylaxis, passive transference of, 160; blood reaction for, 321; chemistry of sputum, 785; chloroform in, 449; commission to fight bovine, 570; conjestion and, 491; county hospital, 442; diabetes and, 780; diagnosis of, 615; diagnostic significance of hemolysis, 991; diet in, 633; disseminated, treated with Marmorek's serum, 920; dystrophies and congenital exostoses, 355; early exanthem in, 783; from a maritime prophylactic point of view, 879; hemorrhage, 323, 497; houses, 567; improvement under sanatorium care, 648; in childhood and its immunity, 920; incipient, 615; infection of, 450; infection of infants, 747; infection through tonsils and adenoids, 322; in infants, 960; in New York, 695; law regulating sanatoria, 488; life insurance, 235, 297; mode of contagion, 786; model tenements for, 823; opsonic index, 1; outlook on, 357; poverty and, 921; Philadelphia Jewish sanatorium, 571; pregnancy and, 243, 439, 615, 1086; prize offered for cure of, 952; prophylaxis of, 1043; relation of enlarged tonsils and adenoids to, 104; relation of infant mortality to, 1002; rate of human contagion in infants, 671; sanitation of, 489; the status of the new tests for, 908; sterilization of pregnant women, 160; toxemia in surgery, 749; vaccination against in 60 cases, 1033; zymosia gastrica, and, 322.
Tuberculosis, of bladder, 75; of bone, 831; of bone, early recognition, 60; of bone, light treatment, 831; of breast, primary, 491; of endocardium, 336; genital, 363; genital in women, 243, 548; of glands, cervical, 790; of glands, treatment with *x*-ray, 790; of glands, importance of early recognition of me-

diastinal, 830; of intestines, diagnosis, 195; of joints, 549; of joints, place for arthrotomy in, 540; of joints, treatment, 330; of knee joint, 448; of kidney, 75, 157, 554, 872; of kidney, surgery of, 177; of larynx, 323; of larynx, supervening upon pneumococcus invasion of the throat, 115; of lungs, amount of involvement at outset, 438; of lungs, based on the assumption that the dietetic cause of the disease is lime starvation, 889; of lungs, creosote treatment, 855; of lungs; diagnosis of, 658; of lungs, early diagnosis of, 351; of lungs, supervening on pneumococcus invasion of the throat, 115; of lungs, tracheobronchial adenopathies in, 84; of nose, 581; of pericardium, operation, 216; skin disease of miners, 618.

Tuberculosis treatment, by artificial pneumothorax, 615; by bismuth paste for sinuses, 541; by immune blood, 875; by mercury, 657; by thyroid extract in, 160; by tuberculin, 528; during past twenty years, 498; sanatorium, 26; temperature as a guide to, 618; use of Marmorek's serum locally, 532.

Tumors, of bladder, 706; of bladder, transperitoneal operation for, 80; of brain, 659; of brain, spontaneous cure, 32, 56; of brain with unusual symptoms, 217; of breast, 82; of cerebellum, removed, 281; etiology of, 321; experimental investigations, 239; growth of, 240; histological classification of, 279; hypophysis, with visual symptoms, 32; intradural of card, 702; of larynx, 118; light, pimentation and, 450; malignant, treated with high-frequency currents, 368; origin of, in uterus, 198; ovarian from lutean cells, 328; of pineal body, 742; pituitary, 957; dermoid simulated by hematoma, 1010; testicle, malignant of undescended, 711; urinary system and cystoscopy, 743; of uterus, 374.

Typhoid, agglutination of Gärtner's bacillus in, 619; analysis of over 68,000 cases, 860; at Cobalt, 743; bacillus in breast milk, 279; carriers, 155, 578; carriers, opsonic index in, 494; Chantemesse ophthalmoreaction in, 282; cholecystectomy for carriers, 578; cost of, 120; diet in, 702; diet and care of the bowels, 248; in New York, 442, 485; isolation of patients, 1040; management of milk-borne epidemics, 877; methods of spreading, 116; nutrition in, 810; preventive inoculations, 744; serum therapy, 822; spine, 575, 874; surgical viewpoint of, 1041; treatment of, 32; treatment by saline instillations, 84; vaccine treatment, 31, 70, 493.

Typhus, prophylaxis, 879.

U.

Ulcer, chronic of leg, treatment of, 603, 959; duodenal, 621, 662, 751; duodenal, perforating, 332; Mooren's, 240; perforating following endarteritis, 616; rodent, 830; stomach, 751; stomach, diagnosis of, 585, 754; stomach, diagnosed by bismuth, 407; stomach, etiology and symptomatology, 752; stomach, latent, 751; stomach, surgery of, 753; stomach, treatment of, 585; stomach, in the young, 754, 827; treatment by scarlet red, 67.

Uncinariasis, 608; commission, 777, 778; commission, in Philippines, 528; in Philippines, 1002.

Unfit, who are the? 213.

University of Tennessee Medical School, 68.

Upright position, mechanics of, 543.

Uremia, treatment, 36, 1004.

Ureter, anatomomorphology of calculus of, 955; vaginal fistula of, 119.

Ureterectomy for a calculus in a dead ureter, 794.

Ureteroniotomy, advantage of combined intra- and extraperitoneal, 706.

Urethra, fragment of filiform removed from, 858; hyperemia by hot sounds, 282; operation on, 121; operation, difficulties in, 363; stricture of, 836; treatment of stricture, 81.

Urethritis, treatment of, 98.

Uric acid, influence of radium on, 75.

Urinary diseases, salt free diet during pregnancy, 831.

Urine, albumin in, 746; ammonia, estimation in, 354; bile pigments, new reaction for, 578; in children, 919; in gastrointestinal disease of infancy, 670; heart failure cells in, 694; indican, practical test for, 701; postoperative suppression of, 659; pressor bases in, 365; tubercle bacilli in, 364.

Ussher, C. D., the therapeutics of calcium sulphide in relation to surgery and contagious diseases, 508.

Utah Medical Association, 612.

Uterus, calcareous degeneration of fibroid, 709; cancer of, 78, 710, 790, 1042; cancer, palliative treatment, 1042; cancer, treatment, 78; cancer, what women should know in regard to, 837; central fixation causing dystocia, 328, 784; death of unexposed interstitial fibroma, 707; elongation of nerves of, 368; fibroid tumors of, 374; fibroid tumor, red degeneration, 75, 155; longitudinal hypertrophy of cervix as a complication of pregnancy and labor, 1033; obstruction, therapeutic drainage of, 292; retroversion and retroflexion, operations for, 756; rupture of, 482, 708; tumors, origin of, 198.

V.

Vacations, 523.

Vaccination, antituberculous, sixty cases, 1033, preventive in dysentery, 960.

Vaccine, pneumococcus in pneumonia, 115, 917; transmission of syphilis by, 879; treatment of furunculosis, 368; typhoid fever, 31, 70.

Vagina, atresia of, 10; cysts of, histology, 119; neuritis and hyperesthesia, 702; rupture of, 482; ureteral fistula of, 119.

Valentine, F. C., and Townsend, T. M., acute gonorrheal prostatitis, 985.

Varicose veins of the leg, 701.

Vasectomy, 1042; for criminals and defectives, 100.

Venereal disease among recent immigrants, 744; peril, is there for us? 896.

Venesection in pneumonia, 501.

Ventilation of industrial establishments, 880; in the tropics, 523; physiological aspects of, 881; sanitary requirements of, 880.

Vermont State Medical Society, 739.

Vertebra, fracture of transverse process of lumbar, 702.

Veru montanum, inflammation of, 364.

Vienna, letter from, 110, 320, 489, 742.

Village treatment for nervous invalids, 435.

Viscera, influence of poise upon the support and function of the, 1086.

Vision, corpus collosum, 872; rôle in evolution, 421; theory of, 575, 703.

Vital statistics, Great Britain, 22.

Vocal cords, sudden death from paralysis of in tertiary syphilis, 920.

Voice, action of respiratory muscles in production of, 582.

Vomiting of pregnancy, 786.

Vulva, neuritis and hyperesthesia, 702.

W.

Wainwright, J. W., anesthesia in the control of inflammation, 472.

Walking tours, effects on school children, 781.

Walsh, J. J., the first American hospital, 562.

Warfield, L. M., secondary carcinoma of the lung, 145.

Washington State Medical Association, 276.

Wassermann tests, in milk, 1044; in orthopedics, 625; in scleroderma, 625; significance of in rhinolaryngology, 786; studies with, 1073; study of 2,750 cases, 1008.

Water of Lake Michigan, 660; protection of supplies, 660; supply to Toronto, 743.

Waterman, P. H., atresia of the vagina, 10.

Watkins, R. L., moving pictures of microscopic objects, 869.

Waugh, W. F., atropine as a hemostatic, 905.

Western Association for the Preservation of Medical Records, 486.

White, F. W., and Bettman, H. W., the clinical results of gastroenterostomy, a preliminary report, 598.

Whooping cough. (See pertussis.)

Wightman, Dr., memorial tablet to, 193.

Williams, Espy, acute gangrenous cholecystitis, gallstone in the cystic duct, perforation of the gall bladder, 861.

Williams, G. H., the after care of the insane, 517.

Williams, T. A., the traumatic neurosis and Babinski's conception of hysteria, 557.

Wisconsin College of Physicians and Surgeons, 109.

Wolbarst, A. L., the value of microscopic examination of the prostatovesicular secretion in the diagnosis and prognosis of gonococcus infection, 304.

Women, glycosuria in, 1044; as health visitors in London, 573; in medicine, 950; Medical Association of Wisconsin, 487; mental disorders of, 650; what they should know regarding uterine cancer, 837.

Wood, Wallace, brain arches, four grand arches of the cerebrum, 141.

Woodruff, C. E., Osler's climatic errors, 999; who are the unfit? 213; the physical decay of Northern Europeans in our Northwest, 1019.

Work in therapeutics, 448.

Worster, W. P., compilation of some facts concerning high frequency currents, 481.

Wuttke, E. E., a clinical and bacteriological study of forty-one consecutive cases of diphtheria, 478.
Wyoming State Medical Society, 525.

X.

X-ray, causing a modification of the neuromuscular electric excitability, 802; dermatitis, 700; desensitizing the skin to, 152; diagnosis of achondroplasia and cretinism, 788; diagnosis of bone disease, 789; diagnosis of pulmonary lesions, 789; diagnosis of urinary calculi, 789; diphtheria toxin and, 785; for general practitioners, 241; for prostatic concretions, 116; in cancer of stomach, 415; in dentistry, 492; speed mania in, 799; in exophthalmic goiter, 1043; in goiter, 790; in gynecology, 355; in infantile leukemia, 1033; injury, amputation for, 1001; in uterine cancer, 790; in hospitals, 790; iron as a substitute for bismuth in, 107; measurement of, 791; of bladder, 367; of mastoid region, 617, 788; some laboratory helps, 790; stereoscopic of chest, 788; value in diagnosis, 1039.

Y.

Yellow fever, in Barbadoes, 527; in Cuba, 982; in Mexico, 879; in Rio de Janeiro, 567; in Tehauntepec, 877; prophylaxis in Cuba, 394; sanitation in the Isthmus, 56; techiness over, 821; utility of domiciliary visits, 877.

Z.

Ziegel, F. L., precocious tertiary syphilis, report of a case with manifold manifestations, 645.
